It is possible in most cases to identify radiographic images of the usual types of flaws in castings. The main types of foundry flaws that can be identified radiographically are described in the paragraphs that follow. Specific examples can be found in reference radiographs, such as those published by ASTM (Table 13).

Microshrinkage appears as dark feathery streaks or dark irregular patches, corresponding to grain-boundary shrinkage. This condition is most often found in magnesium alloy castings.

Shrinkage porosity (spongy shrinkage) appears as a localized honeycomb or mottled pattern (Fig. 61). Spongy shrinkage may be the result of improper pouring temperature or alloy composition.

Fig. 61 Radiographic appearance of gross shrinkage porosity (arrow) in an aluminum alloy 319 manifold casting. Radiograph was made at 85 kV with 1-min exposure.

Gas porosity appears as round or elongated smooth, dark spots. It occurs individually or in clusters or may be distributed randomly throughout the casting. This condition is caused by gas released during solidification or by the evaporation of moisture of volatile material from the mold surface.

Dispersed Discontinuities. Although the flaws usually encountered in light-alloy castings are similar to those in ferrous castings, a group of irregularities called dispersed discontinuities may be present in the former. These dispersed discontinuities, prevalent in aluminum and magnesium alloy castings, consist of tiny voids scattered throughout part or all of the casting. Gas porosity and shrinkage porosity in aluminum alloys are examples of dispersed discontinuities. On radiographs of sections more than 13 mm ($\frac{1}{2}$ in.) thick, it is difficult to distinguish images corresponding to the individual voids. Instead, dispersed discontinuities may appear on film deceptively as mottling, dark streaks, or irregular patches that are only slightly darker than the surrounding regions.

Tears appear as ragged dark lines of variable width having no definite line of continuity. Tears may exist in groups, starting at a surface, or they may be internal. Tears usually result from normal contraction of the casting during or immediately after solidification.

Cold cracks generally appear as single, straight, sharp dark lines and are usually continuous throughout their lengths. Cold cracks are produced by internal stresses caused by thermal gradients and may occur upon cooling from elevated temperatures during flame cutting, grinding, or quenching operations.

Cold shuts appear as distinct dark lines of variable length and smooth outline. Cold shuts are formed when two bodies of molten metal flowing from different directions contact each other but fail to unite. Cold shuts may be produced by interrupted pouring, slow pouring, or pouring the metal at too low a temperature.

Misruns appear as prominent dark areas of variable dimensions with a definite smooth outline. Misruns are produced by failure of the molten metal to completely fill a section of casting mold, leaving the region void.

Inclusions of foreign material in the molten metal may be poured into the mold. They appear as small lighter or darker areas in a radiograph, depending on the absorption properties of the included material as compared to those of the alloy. Sand inclusions appear as gray or light spots of uneven granular texture and have indistinct outlines. Inclusions lighter than the parent metal appear as isolated irregular or elongated variations of film blackening. Occasionally, an inclusion will have absorption characteristics equivalent to those of the matrix and will go undetected, although normally an inclusion that exhibits a radiographic contrast of about 1.4 to 2.3% can be seen. A contrast of 1.4 to 2.3% corresponds to about 0.005 to 0.01 density difference between adjacent areas on the film. Dross inclusions in the outer flange of a casting are shown in Fig. 62.

Fig. 62 Radiographic appearance of dross inclusions (arrows) in the outer flange of a cast aluminum alloy 355

housing body. Radiograph made at 75 kV, 1-min exposure.

Unfused chaplets usually appear in outline conforming to the shape of the chaplet. The outline is caused by a lack of bond between the chaplet and the cast metal.

Core shift can be detected when the view makes it impossible to measure deviation from a specified wall thickness (Fig. 63). Core shift may be caused by jarring the mold, insecure anchorage of cores, or omission of chaplets.

Fig. 63 Uneven wall thickness in an internal passage of a casting caused by core shift (top right). This radiograph, of an aluminum alloy casting about 3 to 6 mm ($\frac{1}{8}$ to $\frac{1}{4}$ in.) thick, was made at 65 kV with an exposure time of 1 min.

Centerline shrinkage is localized along the central plane of a wall section, irrespective of the position occupied by the section in the mold. Such shrinkage is composed of a network of numerous filamentary veinlets leading in the direction of the nearest riser and can sometimes be mistaken for tears.

Shrinkage cavities occur when insufficient feeding of a section results in a continuous cavity within the section. Shrinkage cavities appear on the radiograph as dark areas that are indistinctly outlined and have irregular dimensions.

Segregation is the separation of constituents in an alloy into regions of different chemical compositions. This condition, seen mostly in aluminum alloys, appears as lighter areas on the film that produce a somewhat mottled appearance.

Surface irregularities may produce an image corresponding to any deviation from normal surface profile. It is possible to confuse these with internal flaws unless the casting is visually inspected at the time of interpretation.

Flaws in Weldments

In welding, heat must be carefully controlled to produce fusion and adequate penetration. Too much heat can cause porosity, cracks, and undercutting; too little heat can cause inadequate joint penetration and incomplete fusion.

Most weld flaws consist of abrupt changes in homogeneity and can be readily detected by radiographic inspection. Stresses that are induced in the metal by welding but that are not accompanied by a physical separation of material will not be detected by radiography. Also, cracks not aligned with the x-ray beam may be missed. Conditions that can be detected in welds by radiography are described below. Several reference radiographs of flaws in weldments are provided in the article "Weldments, Brazed Assemblies, and Soldered Joints" in this Volume.

Undercutting appears as a dark line of varying width along the edge of the fusion zone. A fine dark line in this darker area could indicate a crack and should be further investigated.

Incomplete fusion appears as an elongated dark line. It sometimes appears very similar to a crack or an inclusion and could even be interpreted as such. Incomplete fusion occurs between weld and base metal and between successive beads in multiple-pass welds. Incomplete penetration along one or both sides of the weld zone has an appearance similar to that of incomplete fusion.

Cracks are frequently missed if they are very small (such as check cracks in the heat-affected zone) or are not aligned with the radiation beam. When present in a radiograph, cracks often appear as fine dark lines of considerable length but without great width. Even some fine crater cracks are readily detected. In weldments, cracks may be transverse or longitudinal and may be either in the fusion zone or in the heat-affected zone of the base metal. Figure 64 illustrates a large crack in a steel weldment.

Fig. 64 Radiograph showing a large crack in a multiple-pass butt weld in 57 mm ($2\frac{1}{4}$ in.) thick steel plate. The crack mainly follows the edge of the weld, but both ends turn in toward the center. The weld joined a 57 mm ($2\frac{1}{4}$ in.) thick plate to a 70 mm ($2\frac{3}{4}$ in.) thick plate that had been tapered to 57 mm ($2\frac{1}{4}$ in.) at the edge of the weld groove. Radiograph was made with 1-MeV x-rays on Industrex AA film.

Porosity (gas holes) consists commonly of spherical voids that are readily recognizable as dark spots, the radiographic contrast varying directly with diameter. These voids may be randomly dispersed, in clusters, or may even be aligned along the centerline of the fusion zone. Occasionally, the porosity may take the form of tubes (worm holes) aligned along the direction of the weld solidification front. These appear as lines with a width of several millimeters.

Slag inclusions are usually irregularly shaped and appear to have some width. Inclusions are most frequently found at the edge of the weld, as illustrated in Fig. 65. In location, elongated slag deposits are often found between the first root pass and subsequent passes or along the weld-joint interface, while spherical slag inclusions can be distributed anywhere in the weld. The density of a slag inclusion is nearly uniform throughout and has less contrast than porosity, because an inclusion can be considered as a pore with absorbing material. Tungsten inclusions or a very high density (barium-containing) slag will appear as white spots.

Fig. 65 Radiograph showing a crack (dark line at top) and entrapped slag inclusions (dark spots at arrows) on opposite sides of a multiple-pass butt weld joining two 180 mm (7 in.) thick steel plates. Radiograph was made with 1-MeV x-rays on Industrex AA film.

Incomplete root penetration appears as a dark straight line through the center of the weld. The width of the indication is determined by the root gap and amount of weld penetration.

Flaws in Semiconductors

Voids in semiconductors occur in several different sites, depending on the type of construction. In hermetic integrated circuits and low-power transistors, voiding typically occurs at the die (semiconductor element) and header (case) interface. The voids in this area will have the same approximate density as the areas of the header that are undisturbed by the die mount. In hermetic power transistors, voids may occur at the die mount substrate to header interface and at the die to die mount substrate interface. It is not possible to differentiate between interfaces after the device is sealed. Therefore, two radiographs are required--one after substrate attachment and a second after die attachment. Orientation is critical because the radiographs must be compared to determine the total area of voiding. In plastic-encapsulated semiconductors, voids in the encapsulating material are discernible by density differences, just as a void in other materials or in a weld.

Extraneous material is frequently missed because of its small size and very thin cross section. Conductive material as small as 0.025 mm (0.001 in.) in its major dimension may cause failure of a semiconductor device. In some cases, multiple views may be required to determine whether or not expelled die mount material is attached to the device case. Because of the very small geometries used, multiple views may also be required to determine if there is adequate clearance between internal connecting wires.

Electronic devices can also be inspected after they are placed on the circuit board, but the board and its other components will reduce contrast and interfere with the resolution of fine features. The advantage of inspecting after the devices are placed on the board is that connections from the device to the board can be inspected also. Because the solders used to form these joints contain elements of high atomic number, they form high contrast images. Radiographic inspection can detect flaws such as solder balls (undesired solder that has been expelled from the joint), bridging, misregistered devices, and joints without solder. Laminographic systems are available that can emphasize various planes within the circuit board (see the article "Industrial Computed Tomography" in this Volume).

Radiographic Inspection

Revised by the ASM Committee on Radiographic Inspection*

Appendix: Processing of Radiographic Film

In the processing of radiographic film, an invisible latent image produced on the film by exposure to x-rays, γ -rays, or light is made visible and permanent. Film processing is an exacting and important part of the radiographic procedure. Poor processing can be just as detrimental to the quality of a radiograph as poor exposure practice.

Two methods of processing can be employed: manual processing, which is carried out by hand in trays or deep tanks, and automatic processing, which is accomplished in automated equipment. Guidelines for the control and maintenance of manual and automatic radiographic film processing equipment are specified in ASTM E 999.

Manual Film Processing

The manual processing of radiographic film is carried out in a processing room (darkroom) under subdued light of a particular color to which the film is relatively insensitive. The film is first immersed in a developer solution that causes areas of the film that have been exposed to radiation to become dark; the amount of darkening for a given degree of development depends on the degree of exposure. After development, the film is rinsed, preferably in an acid stop bath that arrests development. Next, the film is placed in a fixing solution that dissolves the undarkened portion of the film and hardens the emulsion. The film is subsequently washed to remove the fixing chemicals and soluble salts, then dried.

Although trays and other containers for photographic processing have been used, the usual method of processing industrial radiographic film by hand is the rack-and-tank method. In this method, the processing solutions and wash water are contained in tanks (Fig. 66) deep enough for the film to be hung vertically on developing hangers, or racks. The advantages to this method are:

- Processing solutions have free access to both sides of the film
- Both emulsion surfaces are uniformly processed to the same degree
- The all-important factor of temperature can be controlled by regulating the temperature of the water bath in which the tanks are immersed
- The equipment does not require much space
- There is a savings in time compared to tray processing

Fig. 66 Typical unit for the manual development of radiographic film by a rack-and-tank method. (a) Processing tanks containing developer, stop bath, and fixer. (b) Cascade (countercurrent) washing tank

Handling of Film. The processing room and all equipment and accessories must always be kept scrupulously clean and used only for the purpose of handling and processing film. Spilled solutions should be wiped up immediately to avoid extraneous spots on the radiographs. Floating thermometers, film hangers, and stirring rods should be thoroughly rinsed in clean water after each use to avoid contamination of chemicals or streaking of film.

Film and radiographs should always be handled with dry hands. Abrasion, static electricity, water, or chemical spots will result in extraneous marks (artifacts) on the radiographs. Medicated hand creams should be avoided; rubber gloves should be used.

Development Procedure. Prepared developers are ordinarily used to ensure a carefully compounded chemical that gives uniform results. Commercial x-ray developers are of two types: automatic and manual. Both are comparable in performance and effective life, but the liquids are easier to mix. Developing time for industrial x-ray films depends mainly on type of developer. Normal developing time for all films is 8 min in a given developer at 20 °C (68 °F). More exact tables can be obtained from the manufacturers of developers.

When exposed film is immersed in the developer solution, the chemicals penetrate the emulsion and begin to act on the sensitized (exposed) grains in the emulsion, reducing the grains to metallic silver. The longer the development time, the more metallic silver is formed and the blacker (more dense) the image on the film becomes.

The rate of development is heavily dependent on the temperature of the solution; the higher the temperature, the faster the development. Conversely, if the developer temperature is low, the reaction is slow, and if the film were developed for 5 min at 16 °C (60 °F) instead of the normal 20 °C (68 °F), the resulting radiograph would be underdeveloped. Within certain, rather narrow, temperature limits, the rate of development can be compensated for by increasing or decreasing developing time. Exceeding these temperature limits usually gives unpredictable results.

The concept of time-temperature development should be used in all radiographic work to avoid inconsistent results. In this concept, the temperature of the developer is always kept within a small range. The developing time is adjusted to temperature so that the degree of development remains essentially constant. If this procedure is not followed, the results of even the most accurate radiographic technique will be nullified.

Inspection of the film at various intervals during development under safelight conditions (called sight development) should be avoided. It is extremely difficult to judge from the appearance of a developed but unfixed radiograph what its appearance will be in the dry, finished state, particularly with regard to contrast. Sight development can also lead to a high degree of fog caused by exposure to safelights during development.

A major advantage of standardized time-temperature development is that the processing procedure is essentially constant, and an accurate evaluation of exposure time can be made. This alone can avoid many of the errors that can otherwise occur during exposure. Increased developing time will produce greater graininess in the radiographic image, increased film speed, and in many cases increased radiographic contrast. Although increased contrast or film speed is often desirable, maximum recommended development times should not be exceeded.

Control of Temperature and Time. Because the temperature of the processing solutions has such a large influence on their chemical activity, careful control of temperature--particularly of the developer--is extremely important. A major rule in processing is to check the developer temperature before films are immersed in the developer so that the timer can be accurately set for the correct processing time.

Ideally, the developer should be at 20 °C (68 °F). At temperatures below 16 °C (60 °F), developer action is significantly retarded and is likely to result in underdevelopment. At temperatures exceeding 24 °C (75 °F), the radiograph may become fogged, and the emulsion may be loosened from the base, causing permanent damage to the radiograph.

Where the water temperature in the master tanks surrounding the solution tanks may be below 20 °C (68 °F), hot and cold water connections to a mixing valve supplying the master tank should be used. In warm environments, refrigerated or cooled water may be necessary. Under no circumstances should ice be placed directly into the solution tanks for cooling purposes, because melting ice will dilute, and may contaminate, the solutions. If necessary, ice can be placed in the water bath in the master tanks for control of the solution temperature.

Control of time should be done by setting a processing timer at the time the film is immersed in the developer. The film should be moved to the rinse step as soon as the timer alarm sounds.

Agitation During Development. A good radiograph is uniformly developed over the entire film area. Agitating the film during the course of development is the main factor that eliminates streaking on the radiograph.

When a film is immersed vertically in the developer and is allowed to develop without movement, there is a tendency for certain areas of the film to affect the areas directly below them. The reaction products of development have a higher specific gravity than the developer. As these products diffuse out of the emulsion, they flow downward over the surface of the film and affect the development of the areas over which they pass. As a result, uneven development of affected areas forms streaks, as shown in Fig. 67. This is sometimes referred to as bromide drag. The greater the film density from which reaction products emanate, the greater the effect on adjacent portions of the film.

Fig. 67 Streaking, or bromide drag, that can result when a film is immersed in developer solution without agitation

When the film is agitated, spent developer at the surface of the film is renewed, preventing uneven development. Immediately after hanger and film are immersed in developer, hangers should be tapped sharply two or three times to dislodge any air bells clinging to the emulsion. Although lateral movement of the hanger provides perhaps the best agitation, the size and shape of the solution tanks usually limit the extent of lateral movement, thus making this type of agitation ineffective. Vertical movement works well; it consists of lifting the hanger completely out of the solution, then immediately replacing it in the tank two or three times at intervals of about 1 min throughout the developing time.

Agitation with stirrers or circulating pumps is not recommended. This type of agitation often produces a liquid flow pattern that causes more uneven development than no agitation at all. Nitrogen-burst techniques, although rarely used, can provide adequate agitation.

Activity of Developer Solution. The developing power of the solution decreases when film after film is developed, partly because the developing agent is consumed in converting exposed silver bromide to metallic silver and partly because of the retarding action of accumulated reaction products. The magnitude of this decrease depends on the number of films processed and on their average size and density. Even when the developer is not used, its activity will slowly decrease because of oxidation of the developing agent. The effect of oxidation is often apparent after as little as 1 month of inactivity. Little can be done to control the effects of oxidation except using a lid on the developer tank. Although this is only partly effective in preventing oxidation, it is always good practice to cover developer tanks when not in use in order to prevent contamination.

Replenishment of Developer. If the reduction of developing action is the result of the processing of many films, it is possible to compensate for decreased chemical activity by using a replenishment technique. When done correctly, replenishment can maintain uniform development for a long period of time. Replenishment cannot be used to counteract oxidation or contamination of the developer solution.

Most manufacturers of x-ray developers provide for replenishment either by supplying a separate chemical or by using the developer mixed to a different concentration from that of the original developer solution. The correct quantity of replenisher needed for maintaining consistent properties of the developer solution depends on the size and average density of the radiographs being processed. For example, a dense image over the entire radiograph will use up more developing agents and exhaust the developer to a greater degree than if the film were developed to a lower density. The quantity of replenisher required will depend on the type of subject being radiographed; the following is provided only as a guide:

Density of radiograph	Replenisher
-----------------------	-------------

(% of background exposed)	required ^(a)	
	g	oz
Low (<15%)	57	2
Medium (\sim 40%)	64	$2\frac{1}{4}$
High (\sim 75%)	70	$2\frac{1}{2}$
Extremely high (>90%)	78	$2\frac{3}{4}$

(a) Approximate quantity for each 350 × 430 mm (14 × 17 in.) sheet of film processed

Usually, replenishers are so compounded that drainage of films back into the developer tank should be avoided. The developer being drained is essentially spent; therefore, the developer solution in the tank is more rapidly contaminated with reaction products when this spent solution is drained back.

A systematic procedure should be used so that a fixed quantity of developer is removed from the tank for each film that is developed. A 350 × 430 mm (14 × 17 in.) film mounted on its hanger will normally carry with it 78 to 85 g ($2\frac{3}{4}$ to 3 oz) of developing solution as it is removed from the tank. Because this is approximately the amount of replenisher needed for low-density and medium-density films, it is only necessary to replenish the developer tank to a given liquid level. However, for high-density and extremely high-density radiographs, it would be necessary to remove and discard some of the original developer each time replenisher is added.

If replenisher is added frequently and in small quantities, fluctuations in film density due to changes in chemical activity of the developer will tend to even out. However, if replenisher is added infrequently, a fluctuation in film density will become apparent, which may lead to considerable difficulty in consistently obtaining the required image quality in successively processed radiographs. If replenishment is controlled by maintaining a specific level in the development tank, replenisher should be added when the level of the solution drops by 6 mm ($\frac{1}{4}$ in.).

Arresting Development. After development is completed, the action of the developer absorbed in the emulsion must be arrested by an acetic acid stop bath or at least by prolonged rinsing in clean running water. If these steps are omitted, the developing action continues for a short time in the fixer. This can produce uneven density or streaking on the radiograph and will reduce the life of the acidic fixer solution because of neutralization by the alkaline developer solution.

If the smell of ammonia is detected anywhere--developer, stop bath, or fixer--the solution has become contaminated and must be changed. When development is complete, films should be removed from the developer without draining back.

Films should remain in the stop bath for 30 s with moderate agitation before being transferred to the fixer solution. The stop bath acts as a replenisher for the fixer, so the films can be transferred directly to the fixer without draining back into the stop-bath solution.

If a stop bath is not used, films should be rinsed in running water for at least 2 min. If the flow of water in the rinse tank is only moderate, the film should be agitated so that the rinse will effectively avoid streaks on the radiograph.

Fixing. The purpose of the fixer solution is to remove all of the undeveloped silver salts in the emulsion, leaving the developed silver as a permanent image. Another important function of the fixer is to harden the gelatin of the emulsion so that the film will be able to withstand drying in warm air and will not be tacky to the touch when it is dry and ready for viewing. Portions of the film that have received lower amounts of radiation appear cream colored when the stop-bath procedure has been completed. In the fixing bath, this cream color gradually disappears until it is no longer visible. The interval of time required for this change to take place is called the clearing time. This is the time required to dissolve the undeveloped silver halide out of the emulsion. An equal amount of time is required to allow the dissolved silver salts to diffuse out of the emulsion and the gelatin to harden. The total fixing time, therefore, should be at least twice the clearing time but should not exceed 15 min to avoid loss of density on the film. Films should be agitated vigorously every 2 min during fixation to ensure uniform action of the fixing chemicals.

In performing its function, the fixer solution accumulates soluble salts, which gradually inhibits its chemical activity. As a result of this, and possibly also because of dilution with water, the rate of fixation decreases and hardening action is impaired in proportion to the number of films processed. The usefulness of fixer solution is ended when it loses its acidity or when fixing requires an unusually long interval. At this point, the fixer solution must be discarded. Fixing films in exhausted fixer frequently causes colored stains, known as dichroic fog, to appear on the radiograph. Fixer replenisher is usually available from the manufacturer of the fixer. It is advisable not to substitute brands (or even types) of replenishers for a given brand of fixer; the replenisher may not be compatible with the fixer.

Washing. After radiographic films have been fixed, they should be washed in running water, ensuring that the emulsion area of the film receives frequent changes of water. Proper washing also requires that the hanger bar and top film clips be covered completely by running water.

Effective washing of the film depends on a sufficient flow of water to rapidly carry off the fixer and to allow adequate time for fixer chemicals to diffuse out of the film. In general, the hourly flow of water in the washing tank should be from one to two times the volume of the tank. Under these conditions, and at water temperatures between 16 and 21 °C (60 and 70 °F), films require about 30 min of washing.

The washing tank should be large enough to wash films as quickly as possible. Too small a tank encourages insufficient washing, which may lead to discoloration or fading of the image later when radiographs are in storage.

Drying. When films are removed from washing tanks, water droplets cling to the surface of the emulsion. If the films are then dried rapidly, the areas under the droplets dry more slowly than surrounding areas. Such uneven drying causes distortion of the gelatin, changing the density of the image. Uneven drying often results in visible spots on the finished radiograph that interfere with accurate interpretation.

Water spots usually can be prevented by immersing washed films for 1 to 2 min in a wetting-agent solution and allowing them to drain for a few minutes before placing them in a drier. This procedure permits surplus water to drain off of the film more evenly, significantly reducing drying time and the likelihood that the finished radiograph will exhibit water spots.

It is important to use wetting agents that are compatible with x-ray film emulsions. Some commercial wetting agents are not compatible with film and therefore should not be used.

If only a few radiographs are processed daily, racks that allow the film to be air dried under room conditions of temperature and humidity can be used, although this method of drying requires considerable time. To avoid spots on the radiographs, the racks that hold the film hangers should be positioned so that films do not touch each other, and water should not be splashed on drying films. Radiographs dry best in constantly changing warm dry air.

The fastest way to dry films is in commercial film driers. These driers incorporate fans and heaters, and some driers use chemical desiccants to remove water from the air.

Regardless of the method of drying, a radiograph is considered dry when the film is dry under the hanger clips. When this stage is reached, the hangers are removed from the drier or rack, and the film is carefully removed from the hanger for interpretation.

In manual processing, when the film is clipped to the hanger, pins in the hanger clip penetrate the film and leave sharp projections in the corners of the film. It is usually desirable to cut off the corners containing these clip marks to prevent scratching of other radiographs during handling and reading.

Automatic Film Processing

Although expertly done manual processing is difficult to surpass, it is equally difficult to maintain because of human factors. Automatic processing, which accurately controls temperature, time, agitation, and replenishment, delivers a dry radiograph in a short time. In addition to the advantage of shorter processing time, automatic processing can ensure that variability of time, temperature, and activity of the solutions is eliminated.

Many automatic processors incorporate a roller-transport mechanism that carries the film itself through the entire process cycle without the need for hangers. Figure 68 illustrates a typical automatic processor that incorporates a roller-transport mechanism.

Fig. 68 Cross section of an automatic film processor showing roller-transport mechanism and locations of components

Automatic processing is a carefully controlled system in which the film, processing chemicals and their replenishment, temperature of solutions, travel speed of the roller-transport mechanism, and drying conditions all work together for consistent development of latent images. The advantages of roller-type automatic processors are:

- *Rapid processing of radiographs:* Depending on many variables, particularly the kind of radiographic film and the type of processing chemicals, the elapsed time from exposed film to finished radiograph can be as short as $4\frac{1}{2}$ min and usually not more than 15 min. This represents a savings of at least 45 min compared to manual processing
- *Uniformity of radiographs:* Most automatic processors carefully control the time and temperature of processing. Combined with accurate automatic replenishment of solutions and constant agitation of the

film as it travels through the processor, accurate time-temperature control produces day-to-day consistency and freedom from processing artifacts seldom achieved in manual processing. Because processing variables are virtually eliminated, optimum exposure techniques can be established

- *Conservation of space:* Most models of automatic processors require no more than 1 m² (10 ft²) of floor space. Some models can even be installed on a workbench. This means that hand tanks and drying facilities can be eliminated from the processing room. All that is needed is a bench for loading and unloading of film, film-storage facilities, and a small open area in front of the processor feed tray. Most processors are installed so that the film is fed from the processing room (darkroom) and emerges as a complete radiograph in the adjacent room

Automatic processors contain a developing tank, a fixing tank, a washing tank, and a drying section (Fig. 68). The stop-bath and wetting-agent tanks are eliminated because automatic processors have squeegee rollers at the exit of each tank that reduce retention of residual solution by the film to a minimum, and minor solution contamination of the fixer is corrected by replenishment. The rollers at the exit of the fixer reduce the amount of residual fixer to only that absorbed in the emulsion as the film enters the wash cycle. Therefore, the running wash water is virtually free of fixer chemicals. Finally, the exit rollers of the wash tank squeeze wash water from the film, so that the film enters the drier in almost a damp-dry condition.

Processing chemicals must be specially formulated for automatic processors. The developer must operate at higher temperatures than for manual processing and usually contains a hardening agent to condition the emulsion so that the film can be moved by the roller transport system without slippage. The fixer is also specially formulated to fix the emulsion in a relatively short time at higher temperatures than for manual processing and to condition the film for proper drying. It should be noted that developers and fixers formulated for manual processing usually are not suitable for automatic processing.

Replenishment of Developer and Fixer. In an automatic processor, replenishment of developer and fixer is automatically controlled. An adjustable, positive-metering device controls both developer and fixer; sometimes separate metering devices are used for developer and fixer. Usually, the replenisher pump is activated when the leading edge of the film enters a film sensor in the processor and continues to pump until the trailing edge of the film passes these rollers. Thus, the amount of replenishment is controlled by the length of film passing through the entrance rollers.

Replenishment rates for developer and fixer are normally supplied by film manufacturers. Obviously, these are only guidelines because if radiographs are routinely of higher or lower densities than the average on which the manufacturer's recommendations are based, the replenishment rate may have to be adjusted upward and downward for optimum results.

The procedure for checking replenishment rates and frequency of replenishment is given in the operator's manual for the processor. The accuracy of replenishment is important. Too little or too much replenishment can adversely affect film densities, lead to transport difficulties, reduce processing uniformity, and shorten the useful life of the processing solutions.

Film-Feeding Procedures. Because replenisher pumps are controlled by the length of film fed into the processor, it is obvious that feeding single, narrow-width films will cause excessive replenishment. Therefore, whenever possible, narrower films should be fed side by side. Films should be fed into the processor parallel to the side of the feed tray. Multiple films should have a space between them to avoid overlapping and should be started together into the processor to avoid excessive replenishment.

Three rolls of the roller-transport system must always be in contact with the film to maintain proper travel through the processor. Thus, there is a lower limit to the length of film to be processed. Although this depends on roller diameter and spacing, the usual lower limit is about 125 mm (5 in.).

In general, roll films having widths from 16 to 430 mm (0.6 to 17 in.) can be processed in most automatic processors. The processing of roll films requires a somewhat different procedure than for sheet film. Because roll film is wound on spools, it frequently has an inherent curl that can cause the film to wander out of the roller system. To avoid wandering, a sheet of leader film can be attached to the leading edge of the roll. Ideally, the leader should be unprocessed radiographic film, preferably wider than the roll being processed and at least 250 mm (10 in.) long. The leader may be attached to the roll by means of pressure-sensitive polyester tape about 25 mm (1 in.) wide. Suitable types of tape must be composed of

materials that are not soluble in the solutions. To avoid transport problems, care must be taken that adhesive from the tape does not come in contact with the rollers.

It is important to feed narrow widths of roll film parallel to the edge of the feed tray. If quantities of such film are normally processed, it is usually advisable to provide a guide in the feed tray to make sure each film is parallel to the others and to the sides of the tray. If this is not done, there is a possibility of the films overlapping somewhere in the transport systems.

If only one long roll of narrow film is to be processed, the replenisher pumps will keep running and the result may be excessive replenishment. To avoid this, replenisher pumps should be turned off for a portion of the feed time.

Preventive Maintenance. Most of the downtime and other problems related to the operation of automatic processors stem from the lack of maintenance. Service problems can be minimized by well-established maintenance of the processor and by good housekeeping. Each processor manufacturer recommends daily and weekly cleanup procedures that take only a few minutes to perform. These procedures, usually available in the form of check lists, are necessary for reliable operation of the processor and for production of radiographs of optimum quality.

Precautions. Automatic processing is a system in which the film, chemical, and processing equipment all have to work together for optimum processing. For example, if radiographs leave the processor wet, it could well be an indication of a problem with one of the chemicals and not the result of incorrect drying temperature.

Some films can be successfully processed more rapidly than others. However, changing the speed of the processor to a value other than that for which the processor was designed can unbalance the system and require adjustments in film characteristics, replenishment rates, temperatures, and perhaps other conditions in order to restore optimum processing quality. Care must be taken that the storage life of the radiograph is not impaired by changes in the processor. Table 14 lists some typical problems with automatic film processing.

Table 14 Probable causes and corrective action for various types of deficient image quality or artifacts from automatic film processing

See Table 12 for factors not specifically associated with automatic film processing.

Quality or artifact	Probable cause	Problem and corrective action
Density too high	Overdevelopment	<i>Developer temperature too high:</i> Follow temperature recommendations for developer and processor used. Check temperature of incoming water. Check accuracy of thermometers used.
		<i>Improperly mixed chemicals:</i> Follow instructions for preparations of solutions.
Density too low	Underdevelopment	<i>Improper replenishment of developer:</i> Check for clogged strainers or pinched tubing in developer replenishment system.
		<i>Developer temperature too low:</i> Follow temperature recommendations for developer and processor used. Check temperature of incoming water. Check accuracy of thermometers used.
	Contamination	<i>Fixer in developer tanks:</i> Use extreme care when installing or removing fixer rack in processor. Always use splash guard when fixer rack is being removed or replaced. Do not exchange racks between fixer and developer compartments.
Contrast too low	Underdevelopment	<i>See Underdevelopment above.</i>

	Contamination	See <i>Contamination</i> above.
Fog	Overdevelopment	<i>Developer temperature too high:</i> Follow temperature recommendations for developer and processor used. Check temperature of incoming water. Check accuracy of thermometers used.
Poor drying	Processing	<i>Underreplenishment of solutions (particularly fixer):</i> Check for clogged strainers or pinched tubing in replenishment system.
		<i>Inadequate washing:</i> Check flow of wash water.
Drying	<i>Dryer temperature too low:</i> Follow recommendations for film type and processor involved.	
Streaks	Associated with tempo of work	<i>Long interval between feeding of films:</i> "Delay streaks" (uneven streaks in direction of film travel) caused by interval of 15 min or more in feeding of successive films, which results in drying of solutions on processor rollers exposed to air. Wipe down exposed rollers with damp cloth. Process unexposed 14 × 17 film before processing radiograph. (Some processors are equipped with "rewet rollers" which prevent delay streaks.)
	Associated with development	<i>Clogged developer recirculation system:</i> Change filter cartridge regularly. Check recirculation pump. (This defect is associated with a rapid rise in developer temperature.)
	Associated with dryer	<i>Dirty tubes in dryer:</i> (Causes regular streaks, visible by reflected light only.) Clean dryer tubes.
		<i>High dryer temperature:</i> (Causes irregular streaks or blotches, visible by reflected light only.) Reduce temperature to recommended value.
Guide marks (regularly spaced scratches or high density lines)	Improperly adjusted guides in processor	Check clearances between guide devices and adjacent rollers or other components
Roller abrasions (random fine lines in the direction of film travel)	Stopped or hesitating rollers	Be sure all rollers are in their proper positions, and that end play is sufficient for rollers to turn freely.
Random scratches and spots	Dirt on feed tray	Clean processor feed tray frequently with soft cloth. If the atmosphere is dirty, the processing room should be fed with filtered air and kept at a pressure above that outside.
Irregular deposit (often light in color, generally elongated in direction of film)	Caused by dirt or precipitate in water supplied to washing section.	If condition is temporary, clean wash rack and replace wash water in processor; drain wash tank when shutting processor down. If condition persists, use filters in incoming water lines. (Some dirt deposits can be removed from the dry radiograph by gentle rubbing

travel)		with dry cotton or a soft cloth.)
Dark lines and spots	Pressure marks caused by build-up of foreign matter on rollers or by improper roller clearances, usually in developer section.	Clean rollers thoroughly and maintain proper clearances.
	"Black comets" with tails extending in direction of film travel caused by rust or other iron particles dropping on film, usually at entrance assembly.	Clean all entrance assembly components. Apply a light coat of grease to microswitch springs and terminals. If air contains iron-bearing dust, filter air supply to processing room.
	"Pi lines." (So called because they occur 3.14 times the diameter of a roller away from the leading edge of a film.)	Most common in newly-installed or freshly cleaned processors. Tends to disappear with use of processor. (Some processors are equipped with buffer rollers at the exit of the wash rack, which remove the deposit before the radiograph enters the dryer.)

Tests for Removal of Fixer

If radiographic films are not properly washed, fixer chemicals (largely thiosulfate salts) remain in the emulsion and affect the storage life of the radiographs. Radiographs intended for storage of 3 to 10 years are usually referred to as having commercial quality. Those to be kept for 20 years or more are known as having archival quality. Archival quality is of considerable importance in complying with certain codes, standards, and specifications. If residual thiosulfate in the radiographs exceeds a certain maximum allowable level, the radiograph is likely to become useless because of fading or a change in color during long-term storage.

The American National Standards Institute has three important documents relating to this problem: ANSI PH 4.8 (1985), ANSI PH 1.41 (1984), and ANSI PH 1.66 (1985).

The first document (ANSI PH 4.8) describes two methods of determining residual thiosulfate in radiographs. Both of these are laboratory procedures for evaluating unexposed but processed (clear) areas of a radiograph. The methylene blue test must be performed within two weeks of processing the film, but the silver densitometric test can be performed at any time after processing. The second document (ANSI PH 1.41) specifies, among other things, the maximum level of thiosulfate in grams per unit area for archival storage. The third document (ANSI PH 1.66) gives other helpful recommendations for storage of radiographs. Procedures given in all three ANSI documents are accepted as valid procedures by most codes, standards, and specifications.

There are other tests that are easier to perform than those described in ANSI PH 4.8, but they indicate more than the residual level of thiosulfate and therefore are considered only estimates rather than accurate determinations. In one test, a solution is made of 710 mL (24 oz) of water, 120 mL (4 oz) of acetic acid (28%), and 7 mL ($\frac{1}{4}$ oz) of silver nitrate and diluted with 950 mL (32 oz) of water prior to use. When a drop of the diluted solution is placed on a clear area of a radiograph, it turns brown. The amount of residual fixer chemicals is estimated by matching the brown spot on the film with one of the patches on a standard test strip. Several manufacturers produce estimating kits, but for accurate determination of residual thiosulfate it is necessary to perform either the methylene blue test or the silver densitometric test described in ANSI PH 4.8.

Microfilming of Radiographs

The microfilming of radiographs has recently been implemented on a commercial basis for the storage of industrial radiographs, and it has been in use for some time in the medical field. The microreduction of radiographs has been successfully performed by the commercial nuclear power plant industry as a solution to problems associated with radiographic film deterioration, large-volume archival storage, and general records management.

Because of improper initial processing or failure to store and handle processed film using sound practices, radiographs are subject to deterioration or degradation. Specific examples of improper processing include:

- Inadequate replenishment of chemicals (developer and fixer in particular)
- Failure to maintain processing temperatures within manufacturer's specified ranges
- Inadequate agitation
- Rushing processing times
- Failure to maintain water quality

The consequences can be failure to remove thiosulfate, resulting in a green, yellow, amber, or brown tint or image destruction, and failure to remove uncombined silver resulting in general darkening of the image.

Examples of poor storage and handling practices include:

- Handling radiographs without the use of gloves to protect the film from acids, chemicals, and perspiration on the hands
- Placing rubber bands or paper clips on the film
- Storing hard copy information produced using a diazo process with film
- Stacking film, especially film not interleaved, causing it to adhere
- Filing wet film
- Placing inventory or acceptance punches in the area of interest
- Failure to store the radiographs in low-humidity/room-temperature conditions
- Failure to store radiographs in acid-free interleaving paper

The microfilming of radiographs has been used to transfer the deteriorated or degraded image to a stable, archival medium. Microfilming is performed using a planetary camera system with illuminators to photograph the radiographic image on 35 mm roll format. Spatial resolutions in excess of 120 line pairs per millimeter (or <0.0003 in.) on the resulting image have been produced. With a reduction factor of 15:1, information on the original radiograph in the range of 8 line pairs per millimeter (or a resolution of 0.005 in.) has been reproduced within a density of 4.0 (Fig. 69), and spatial resolutions as high as 11 lines per millimeter (0.0035 in.) have been produced at lower densities.

Fig. 69 Spatial resolution versus optical density for a microfilm (15:1 reduction) of a radiograph with a spatial resolution in the range of 8 line pairs per millimeter (or 0.005 in. resolution)

Because of the wide range of optical densities associated with industrial radiographs and the inability of high-resolution microfilms to reproduce wide latitudes of density, the microfilming of radiographs may involve one or more exposures of the same radiograph to capture all of the information present. Sensitometry checks of the process result in density capture ranges (accurate contrast reproduction) as high as 1.5 density points per exposure.

Special viewing equipment is necessary for use with the microfilm. Equipment is available that will allow accurate dimensional measurements from the microfilm, density determination, binocular viewing, and adjustable light intensities, as with a typical radiograph viewer.

Introduction

COMPUTED TOMOGRAPHY (CT), in a general sense, is an imaging technique that generates an image of a thin, cross-sectional slice of a testpiece (Fig. 1a). The CT imaging technique differs from other imaging methods in that the energy beam and the detector array in CT systems lie in the same plane as the surface being imaged. This is unlike typical imaging techniques, in which the energy beam path is perpendicular to the surface being imaged. Moreover, because the plane of a CT image is parallel with the energy beam and detector scan path, CT systems require a computing procedure to calculate, locate, and display the point-by-point relative attenuation of the energy beam passing through the structures within the thin, cross-sectional slice of the testpiece.

Fig. 1 Comparison of computed tomography (a) and radiography (b). A high-quality digital radiograph (b) of a solid rocket motor igniter shows a serious flaw in a carefully oriented tangential shot. A CT image (a) at the height of the flaw shows the flaw in more detail and in a form an inexperienced viewer can readily recognize. Courtesy of J.H. Stanley, ARACOR

Computed tomography has been demonstrated with a number of different types of energy beams, such as ultrasound, electrons, protons, α particles, lasers, and microwaves. In industrial nondestructive evaluations (NDE), however, only x-ray computed tomography is considered to have widespread value. X-ray computed tomography collects and reconstructs the data of x-ray transmission through a two-dimensional slice of an object to form a cross-sectional image without interference from overlying and underlying areas of the object. The CT image represents the point-by-point linear attenuation coefficients in the slice, which depend on the physical density of the material, the effective atomic number of the material, and the x-ray beam energy. The CT image is unobscured by other regions of the testpiece and is highly sensitive to small density differences ($<1\%$) between structures. Computed tomography systems can also produce digital radiography (DR) images, and the DR and CT images can be further processed or analyzed within the computer. A series of CT images can be used to characterize the object volume, with the data reformatted to display alternate planes through the component or to present three-dimensional surfaces of structures within the object.

Historical Background

Although the mathematical principle of computed tomography was developed early in this century by Radon (Ref 1), application of the technology occurred much later. Techniques were developed in the 1950s for radioastronomy (Ref 2), and experimental work progressed through the 1960s, primarily using nuclear tracer and electron microscopy data (Ref 3, 4, 5). In the late 1960s and early 1970s, G. Hounsfield at EMI, Ltd., in England developed the first commercial x-ray CT system, also known as a computerized assisted tomography (CAT) scanner (Ref 6). Commercial CT scanners also found increased acceptance with the availability of inexpensive computing power, and industrial testing was considered an appropriate application in this early development of commercial CT systems. These early efforts, however, were directed primarily toward applications for medical diagnostic imaging. There was some limited use of computed tomography in the 1970s for industrial and research applications; this work was primarily done on existing medical systems.

Since the end of the 1970s, dedicated efforts have been applied to the use of computed tomography in industry. The petroleum industry was one of the early major users of medical-type scanners to analyze oil drilling core samples and to assist in analyzing secondary oil recovery methods in rock samples. Medical CT systems in hospitals and industry are also used to nondestructively test industrial components, primarily carbon composite materials and light metal alloy structures (Ref 7). Diagnostic medical scanners, however, are designed for a specific task. They provide high-quality images of the human body, but are not suitable for large, dense objects.

Industrial CT systems are now manufactured to address specific inspection objectives that extend beyond the capabilities of medical computed tomography. Key differences may include the ability to handle dense materials and larger objects, the use of higher-energy x-ray sources, the use of systems with higher resolution, and the ability to operate within the manufacturing environment. The U.S. military services have actively driven the development of dedicated industrial CT systems. In the late 1970s and early 1980s, several programs were initiated with specific inspection objectives. Early programs included systems for inspecting large rocket motors, and systems for inspecting small precision castings in aircraft engines. Since these early systems, advancements have been made to extend the range of capabilities and applications.

Basic Principles of Computed Tomography

The basic technique of computed tomography is illustrated in Fig. 2. A thin slice of the testpiece is interrogated with a thin beam of radiation, which is attenuated as it passes through the testpiece. The fraction of the x-ray beam that is attenuated is directly related to the density and thickness of material through which the beam has traveled and to the composition of the material and the energy of the x-ray beam. Computed tomography utilizes this information, from many different angles, to determine cross-sectional configuration with the aid of a computerized reconstruction algorithm. This reconstruction algorithm quantitatively determines the point-by-point mapping of the relative radiation attenuation coefficients from the set of one-dimensional radiation measurements.

Fig. 2 Schematic of a computed tomography process

dimensional distribution can be reconstructed from the infinite set of its line integrals through the distribution. (A line integral in CT is the sum of linear attenuation coefficients for one ray of radiation transmitted across the length of a cross-sectional slice.) The iterative techniques are generally algebraic methods that reconstruct the two-dimensional image by performing iterative corrections on an initial guess of what the image might look like. Iterative methods are rarely used, except when only limited data are available (as when a weak γ -ray source would require an inordinate amount of time in obtaining measurements from many scanning angles).

Some of the techniques used in CT image reconstruction are discussed in Appendix 1 in this article. The method most commonly used is the filtered (or convolution) back-projection technique. This technique filters (or convolutes) the projection data and then backprojects the filtered data into the two-dimensional image matrix. The backprojection process is the mathematical operation of mapping the one-dimensional projection data back into a two-dimensional grid, and it is equivalent to smearing the filtered projection data through the corresponding object space (Fig. 3b). The backprojected image values are calculated by taking each point in the image matrix and summing all filtered projection values that pass through that point. The sharpening filter is applied to the measured projection data to compensate for the blurring of the image that is a consequence of the backprojection process (Fig. 3a). Additional information on the basic concepts of reconstruction processing are presented in Appendix 1, along with references to more detailed descriptions of the mathematical reconstruction processes. A glossary of terms and definitions is provided in Appendix 2.

The CT scanning system contains a radiation source and radiation detector along with a precision manipulator to scan a cross-sectional slice from different angles. The x-ray detector is usually a linear array, that is, a series of individual x-ray sensors arranged in a line. The x-ray source is collimated to form a thin fan beam that is wide enough to expose all of the detector elements (Fig. 1a). The narrow beam thickness defines the thickness of the cross-sectional slice to be measured. The data acquisition system reads the signal from each individual detector, converts these measurements to numeric values, and transfers the data to a computer to be processed. To obtain the full set of transmission data required to produce the CT image, the object, source, or detector moves while a sequence of measurements is made. This motion may involve rotation of the test object relative to the source and the detector array (Fig. 1a) or a combination of rotation and translation. The various types of scanning geometries are discussed in the section "CT System Design and Equipment" in this article.

The CT image reconstruction algorithm generates a two-dimensional image from the set of one-dimensional radiation measurements taken at different scanning angles. The reconstruction algorithms used to generate the CT image fall into two groups: transform techniques and iterative techniques. The transform techniques are generally based on the theorem of Radon, which states that any two-

Fig. 3 Schematic of CT image reconstruction by (a) simple backprojection and (b) filtered backprojection. (a) Simple backprojection produces a blurred and broadened image. (b) Filtering can subtract the smear from other projections and reduce the broad blurring when backprojection is performed from many angles.

The CT Image. The CT reconstruction process yields a two-dimensional array of numbers corresponding to the cross section of the object. Each of these numbers is a pixel or picture element, in the cross-sectional image (Fig. 4c). The reconstructed image is an array of many pixel values per image, and the arrays have sizes such as 128×128 , 256×256 , 512×512 , or 1024×1024 pixels per array. Because the scan transmission measurements are made with an x-ray beam of some thickness (Fig. 4a), pixel value in the two-dimensional image corresponds to a volume of the material in the object referred to as a voxel, or volume element (Fig. 4b).

Fig. 4 Components of a CT image. (a) The x-ray transmission measurements and resultant CT image correspond to a defined slice through the object. (b) The cross-sectional slice can be considered to contain a matrix of volume elements, or voxels. (c) The reconstructed CT image consists of a matrix of picture elements, or pixels, each having a numeric value proportional to the measured x-ray attenuation characteristics of the material in the corresponding voxel.

The pixel values are usually an integer value that is proportional to the average linear x-ray attenuation coefficient of the material in the corresponding voxel. The linear attenuation coefficient is approximately proportional to the physical

density of the material and is a function of the effective atomic number of the material and the spectral distribution of the x-ray beam. Because these pixel values are more or less proportional to the density of the material, they are sometimes referred to as density or x-ray density values. This is a useful concept in interpreting images, but it is necessary to remember that other factors affect this value when objects contain multiple materials or when images obtained at different energies are compared.

The scaling of the linear attenuation coefficient into an integer pixel value, as well as the range of coefficients covered by the CT number scale, is somewhat arbitrary among systems. Medical systems utilize an offset scale that is normalized to water. These systems assign air a CT value of -1000, water is at 0, and a material twice as attenuative as water has a CT value of + 1000. Industrial CT systems normally set the value for air at 0, but no standard scaling of the CT values is applicable to all the various materials and x-ray energies used.

To permit interpretation of the information in the reconstructed array of numbers, this information is displayed visually as an image. Human perception is limited, however, and cannot distinguish the many thousands of density levels that may be present in a single image. For distinguishing small density differences over a wide range of densities, the display system uses an interactive CT number windowing capability. This display windowing presents a limited range of CT numbers over the full gray-scale range of the visual display and is a powerful tool in analyzing subtle features in the image data. Color can also be used to enhance the displayed image where ranges of CT numbers are presented as a particular color. The color scales can be set up as a rainbow of colors, as hues of a particular color, or as a hot body spectrum mimicking the colors emitted as an object is heated.

Industrial Computed Tomography

Capabilities

X-ray computed tomography is a radiological procedure and has many of the same considerations as film and real-time radiography. The system must be designed to permit sufficient penetration of the x-rays through the object. Radiation shielding is required as part of the system or installation. Immersion is not required, and air gaps, multiple materials, complex shapes, and surface irregularities do not present a significant difficulty. The displayed parameter corresponds to the linear attenuation coefficient of the materials within the test specimen, and structures differing by a fraction of a percent can be visualized. In a CT image, the structures of interest are not obscured by other structures, and the sensitivity and ability to detect a feature are less dependent on the presence and overall thickness of other structures.

Because the CT image corresponds to a thin section through the object, features can be localized in three dimensions. This can be highly valuable in determining whether a flaw is within a critical area and in providing specific information on the reparability of a component and how the repair should be implemented. This spatial information also permits one to make certain dimensional measurements from the image that may otherwise be difficult or impossible to obtain nondestructively. The ability to provide spatially specific structure and density information also opens up the opportunity to obtain three-dimensional data representations of physical components for computer-aided design documentation and computer-aided engineering analysis.

Computed tomography also has its limitations. Producing high-quality images requires a stable radiation source, a precise mechanical manipulator, a sensitive and highly linear x-ray detector system, considerable computing power (usually with highspeed array processors), and a high-quality image display. Consequently, the capital costs for industrial CT systems tend to be well above those of most routine inspection systems.

The fact that the CT image corresponds to a thin section through the testpiece provides beneficial information and sensitivity. This can produce throughput difficulties, however, if information is required over a large volume. Many thin CT slices are required for fully characterizing an entire component. Typically, full-volume CT scanning is limited to certain low-volume, high-value testpieces or to the engineering evaluation of prototype or test specimens. In higher-volume production, CT images are often taken at specific critical positions for flaw detection or dimensional analysis. The digital radiography mode of these systems or some other conventional inspection technique is often used to identify suspicious indications, and CT imaging is used to characterize the structure or flaw to provide more information for the accept/reject/repair decision on the component.

Another limitation of industrial computed tomography does not pertain to its ability to provide specific information but to the relative newness of the technology and the ability to obtain and use CT information. Critical inspections are normally defined as part of a component design, and prior designs did not consider the potential of computed tomography. Inspection requirements can be changed, but must be done on a component-by-component basis. This has limited much of the use of computed tomography for existing components to in-process inspection for process control and minimizing scrap costs or to providing improved information for material-review decisions.

Some of the current component designs require CT inspection to ensure reliability, to reduce the assumed maximum contained defect used in the design, or to design structures that do not provide good access for ultrasonic or routine radiographic inspection. This ability to characterize the interior structures of complex shapes and assemblies reduces the constraints for inspectability and therefore provides design engineers with the freedom to design.

Detection Capabilities. The ability to present a density (or linear attenuation coefficient) map across a slice through a specimen allows the visualization of many types of structures and flaws. The ability of computed tomography to display specific features will vary with the capabilities of the specific system and the operating parameters used to obtain the image. Assuming adequate capabilities for a particular scanning situation, some generalizations can be made regarding the suitability of computed tomography for various flaw types:

- Voids and inclusions are readily detectable high-contrast targets. Targets considerably smaller than the resolution of the system can be seen, but will have less contrast from the background material. High-structure noise, as in composites, can further limit the detectability of small voids or inclusions
- Porosity and microshrink reduce the density of the material and are usually visible if distributed over a multipixel area. The percentage of porosity can be quantified with properly controlled procedures
- Relative density measurements for a material or for materials with the same effective atomic number can be made. Absolute density can be obtained with properly controlled procedures. Alternative techniques, such as dual energy scanning, may improve capabilities with multiple materials
- Separated or displaced cracks are detectable. As with voids, the separation may be well below the resolution of the system, but contrast will drop as the separation decreases. Detectability may be affected by structure noise or if the crack is adjacent to a high-contrast boundary
- Disbonds and delaminations are detectable if separated. They are similar to cracks, with the additional complication of adjacent structures with the same orientation
- Residual core material in castings is readily seen in bulk. Thin surface layers can be difficult to detect
- Machining defects, such as overdrills and scarfing grooves, are readily seen. Computed tomography can assist in quantifying the extent of machining defects

Industrial Computed Tomography

Michael J. Dennis, General Electric Company, NDE Systems and Services

Comparison to Other NDE Methods

X-ray computed tomography provides one method of detecting and locating the internal flaws of a testpiece. Other common NDE methods of internal flaw detection and location include radiography and ultrasound, which are compared with x-ray computed tomography in Table 1. Less common methods in industrial testing are nuclear tracer imaging, nuclear magnetic resonance imaging, and x-ray backscatter imaging. Acoustic emission, holography, and other techniques provide indirect or bulk information on the internal structure without specifically defining the structure.

Table 1 Comparison of ultrasound, radiography, and x-ray computed tomography

Performance characteristic	Ultrasound	Radiography	Computed tomography

Parameter imaged	Acoustic impedance differences, attenuation, velocity	Attenuation	Attenuation
Handling	Immersion, squirter	Flexible	Scanner size limitation
Surface roughness	Poor	Fair	Good
Complex structures	Poor	Fair	Good
Limitations	Needs acoustic coupling; not suitable for acoustically noisy materials	Penetration one side	Penetration over a 360° scan; limited volume imaged per scan
System costs	Medium	Medium	High
Flaw detection			
Voids	Good	Good	Good
Inclusions	Good	Fair	Good
Porosity and microshrink	Good	Fair	Good
Density variations	Fair	Fair	Good
Cracks	Good (not aligned)	Fair (separated and aligned)	Fair (separated)
Debonds	Good	Fair (separated and aligned)	Fair (separated)

Computed Tomography and Radiography. X-ray computed tomography is a radiological technique, and has many of the same benefits and limitations as film and real-time radiography. The primary difference is the nature of the radiological image. Radiography compresses the structural information from a three-dimensional volume into a two-dimensional image. This is useful in that it allows a relatively large volume to be interrogated and represented in a single image. This compression, however, limits the information and reduces the sensitivity to small variations. Radiographic images can be difficult to interpret because of shadows from overlying and underlying structures superimposed on the features of interest. Further, a single radiographic image does not provide sufficient information to localize a feature in three dimensions. Some of the performance characteristics of radiography and computed tomography are compared in Table 2.

Table 2 Comparison of performance characteristics for film radiography, real-time radiography, and x-ray computed tomography

Digital radiographic imaging performance with discrete element detector arrays is comparable to CT performance values.

Performance	Film radiography	Real-time radiography ^(a)	Computed tomography
-------------	------------------	--------------------------------------	---------------------

characteristic			
Spatial resolution ^(b)	>5 line pairs/mm	~2.5 line pairs/mm	0.2-4.5 line pairs/mm
Absorption efficiencies, %			
Absorption efficiency (80 keV)	5	20	99
Absorption efficiency (420 keV)	2	8	95
Absorption efficiency (2 MeV)	0.5	2	80
Sources of noise	Scatter, poor photon statistics	Scatter, poor photon statistics	Minimal scatter
Dynamic range	200-1000	500-2000	Up to 1×10^6
Digital image processing	Poor; requires film scanner	Moderate to good; typically 8-bit data	Excellent; typically 16-bit data
Dimensioning capability	Moderate; affected by structure visibility and variable radiographic magnification	Moderate to poor; affected by structure visibility, resolution, variable radiographic magnification, and optical distortions	Excellent; affected by resolution, enhanced by low contrast detectability

(a) General characteristics of real-time radiography with fluorescent screen-TV camera system or an image intensifier.

(b) Can be improved with microfocus x-ray source and geometric magnification.

Nuclear Tracer Imaging. Both nuclear imaging and magnetic resonance imaging are widely used for medical diagnostic imaging, but are infrequently used for industrial structural imaging. Nuclear tracer imaging yields an image of the distribution of a radioactive substance within an object. It has the potential for imaging flow paths through a structure or for the absorption of the tracer in open, porous areas of the object. Tracer studies obviously require the capability to handle unsealed radioactive materials, and the images are affected by the attenuating structure of the object between the tracer and the detector. Nuclear tracer imaging comprises two different advanced CT techniques that are similar to x-ray computed tomography. These are single photon emission computed tomography (SPECT) and positron emission tomography (PET) scanning, which produce cross-sectional displays of the tracer concentration (Ref 8).

Nuclear magnetic resonance (NMR) imaging, or magnetic resonance imaging, is similar to x-ray computed tomography in the type of images produced and in some of the methods for processing the NMR data. For NMR imaging, the object is placed in a strong magnetic field. The magnetic dipole of certain nuclei, such as hydrogen, will tend to line up with the magnetic field. These nuclei will precess, or rotate, at a particular frequency that is dependent on the nuclide and the magnetic field strength. Adding energy in the form of radiowaves at this specific resonance frequency will cause the nucleus to be pushed out of alignment with the magnetic field. The nucleus, after some short period of time, will then fall back into alignment with the magnetic field and emit a radiowave in the process. The emitted radiowaves are

monitored, the time constants measured, and the magnetic fields varied in order to produce cross-sectional images of the particular nuclide being monitored.

Nuclear magnetic resonance imaging has been highly successful for the diagnostic medical imaging of the water-based human body, but has severe limitations for most industrial imaging requirements. Nuclear magnetic resonance is sensitive only to nuclides with a nuclear dipole moment, that is, nuclei with an odd number of protons or neutrons. The nuclide of interest is generally required to be in a liquid or gelatinous state because the time constants for solids are too short. In addition, the object cannot contain ferromagnetic materials, which would disrupt the uniform magnetic field, nor can it contain highly conductive materials that would interfere with the transmission of the radiowaves. This technique has appeared useful for analyzing fluids in rock samples for the petroleum industry (Ref 9, 10). Some limited work has been demonstrated for industrial testing in which a liquid tracer, such as alcohol, was used to image the porosity within carbon composite structures (Ref 11, 12).

Backscatter or Compton imaging is a technique in which the object is irradiated by a narrow x-ray beam, and the Compton scattering of this radiation by the object is monitored (Ref 13). The amount of scattered radiation produced is directly related to the electron density of the material, which corresponds well to the physical density of the material.

The proportion of the x-ray beam scattered in a small volume of the object tends to be relatively small, and the x-rays are scattered in all directions. A portion of this scattered radiation is measured by detectors typically placed near the entry point of the x-ray beam.

In general, radiography or computed tomography is preferred for internal inspection where it is practical to use. The major advantage offered by backscatter imaging is that it can be implemented from one side of the object. Other x-ray imaging methods require the source on one side of the object and the film or detector on the opposite side in order to measure x-ray transmission. Backscatter imaging provides a means of obtaining near-subsurface information, particularly if the object is very massive, does not permit x-ray transmission through it, or does not permit access to the opposite side (Ref 14, 15). Like computed tomography, backscatter imaging can also generate images of planar sections through the testpiece.

Industrial CT Applications

Computed tomography provides a unique means of obtaining very specific information on the interior structure of components. Computed tomography technology is very versatile and is not restricted by the shape or composition of the object being inspected. Also, CT systems can be configured to inspect objects of greatly varying sizes, weights, and densities. Generally, systems designed to accommodate large objects do not provide spatial resolution as high as systems designed for the inspection of smaller objects.

The major limitations of computed tomography are the relatively high equipment costs and the limited throughput for evaluating large volumes. Although CT systems improve sensitivity by generating images of a thin cross section, this procedure also produces throughput difficulties if information is required over a large volume. Many thin CT slices are required for the full characterization of an entire component. Typically, full-volume CT scanning is limited to certain low-volume, high-value components or to the engineering evaluation of prototype or test specimens. In higher-volume production, CT images are often taken at specific critical positions for flaw detection or dimensional analysis. The digital radiography mode of CT systems (see the section "Special Features" in this article) or some other conventional inspection technique is often used to identify suspicious indications. The CT imaging mode is then used to characterize the structure or flaw to provide more information for the accept/reject/repair decision on the component.

The petroleum industry uses computed tomography for geological analysis and for fluid dynamics research studies (Ref 16, 17, 18, 19, 20, 21, 22). Rock core samples are obtained from drilling sites to evaluate the oil production capabilities of a well. Computed tomography can be used to help evaluate these core samples with regard to heterogeneity, fracturing, or contamination by the drilling process. Small plugs are often taken from these core samples for extensive analysis of porosity, permeability, oil content, and other parameters. The CT data can assist in locating appropriate areas for these plug samples and in avoiding nonrepresentative samples and erroneous results.

Computed tomography is also used in dynamic flow studies of oil well core samples. The improved understanding of oil flow through the rock and the use of water, carbon dioxide, surfactants, and other chemicals to push the oil to a production well can have significant economic benefits. The test core samples are placed in sealed containers with the appropriate plumbing, and the flow experiments can be conducted at high pressures and elevated temperatures to simulate reservoir conditions.

The flow rates are typically slow, and a study can last many hours. A series of CT slices is obtained at various times in the study to characterize the fluid position. To distinguish the various fluids, contrast media or highly attenuating dopants, such as iodine, can be added to one of the fluids. The resulting data are processed to determine the percentage of saturation or volume concentration of the various fluids and gases present (Fig. 5). Dual energy imaging is sometimes used to assist in quantifying these fluid concentrations. Dual energy imaging uses CT scans of a section acquired at different x-ray energies to evaluate the effective atomic number of the materials present.

Fig. 5 CT image of a rock sample with oil and water. The lighter circular areas at the top and right are areas containing water, while the darker regions at the bottom and left are areas with oil. Courtesy of B.G. Isaacson, Bio-Imaging Research, Inc.

Another research example in the energy industry was a U.S. Department of Energy funded study of the process of burning coal (Ref 23). In this study, a controlled furnace was placed in a medical CT system. The thermal fronts and relative density changes were imaged by computed tomography while the effluent gases and other parameters were monitored.

Composite structures, by their nature are complex materials that can pose challenges in design, fabrication, and inspection. Because of the high strength-to-weight ratio of these materials, composite usage is increasing, especially in the weight-sensitive aerospace industry. Computed tomography imaging has found considerable use in assisting the engineering development, problem solving, and production of composite components (particularly carbon composite components). The ability to track the integrity of individual components can greatly simplify process analysis relative to a sampled destructive study.

Computed tomography has been used to evaluate the fabrication process for certain composite components, including molded chopped-fiber components, as shown in Fig. 6. Resin flow patterns (Fig. 6) can be seen, and an individual component can be evaluated at different stages of curing to determine the point at which processing defects are created in the component. Resin flows in composite materials are generally visible, assuming a difference in the linear attenuation coefficient between the fiber and resin material. Low-density resin flows with widths near the image resolution may appear similar to a crack with subresolution separation. The use of dual energy techniques may help in distinguishing between similar indications. Fiber orientation in composite materials is sometimes seen, especially with chopped-fiber molded components. The ability to discriminate individual fiber bundles is highly dependent on fiber bundle size and system resolution. Computed tomography can detect indications of waviness in composite layers and porpoising (out-of-plane waviness). Radiographic tracer fibers appear with very high contrast.

Fig. 6 CT image of a molded chopped-fiber carbon composite showing a resin flow (left) and a void in the center rib

Operational tests and tests to failure can also benefit from detailed data obtained at various stages of the test. One example of this type of use is the evaluation of rocket motor nozzles before and after firing tests (Ref 24). In this case, the degree and depth of charring were evaluated and compared with theoretical models. Computed tomography has been used in a number of situations to assist in the evaluation of valuable prototype components.

Some of the highest interest in the use of new techniques occurs with engineering problem solving. An example is the failure of the space shuttle launched communication satellites to obtain proper orbit in February 1984. In this case, computed tomography demonstrated interlaminar density variations (Fig. 7b) in some of the rocket motor exit cones of the type used with the satellites. These variations had not been detected by routine inspection of the components. Computed tomography provided a mechanism to evaluate the existing inventories, permitting judgments to be made on the flight-worthiness of the remaining hardware (Ref 25).

Fig. 7 Digital radiograph (a) of rocket exit cone showing the position for CT scanning through the thread portion of the component. (b) CT image through threaded area of rocket exit cone. CT revealed the extent of interply density variations.

Computed tomography is also used in the production inspection of certain composite hardware. This is particularly true in the case of composite rocket motor hardware because of the experiences discussed above and the active role governmental agencies have played in driving this capability. The increased use of composite materials in critical structures is increasing the role of computed tomography in the production inspection of composite components.

Rocket Motors. In addition to individual rocket motor composite components, CT systems are used to scan full rocket motors. Some of these systems use linear accelerator x-ray sources up to 25 MV and are designed to inspect solid propellant rockets in excess of 3 m (9.8 ft) in diameter. These systems can be used to evaluate the assembly of the various motor components and to evaluate the integrity and fit of the casing, liners, and propellant (Ref 26, 27).

Precision Castings and Forgings. Computed tomography systems are used for the production inspection of small, complex precision castings and forgings, especially turbine blades and vanes used in aircraft engines and liquid propellant rocket motor pumps. The ability to localize material flaws and passage dimensions has also permitted the reworking of complex castings and fabrications. In the aircraft engine industry, computed tomography is considered an enabling technology that will allow large, complex structural castings to replace fabricated components, reducing both component weight and manufacturing costs. Computed tomography is also used to analyze the wall thickness of certain used blades to evaluate if sufficient material remains for refurbishing the component. This has permitted the overhaul and reuse of components that would otherwise be questionable.

Flaw Detection. Because of throughput considerations for production, casting flaws are generally detected in the digital radiography mode (see the section "Special Features" in this article for a discussion of the digital radiography mode). Computed tomography is used to detect flaws in critical areas and to further evaluate flaw indications detected by digital radiography or other methods (Ref 27, 28, 29). The specific data provided by computed tomography for the evaluation of flaw indications allow for a more informed accept/reject decision. Porosity and microshrink reduce the density of the material and are usually visible if distributed over a multipixel area (Fig. 8). The percentage of porosity can be quantified with properly controlled procedures. Other detectable conditions include casting bridges or fins, residual core material in the casting (Fig. 9a), and machining defects (Fig. 9b).

Fig. 8 CT image of cast housing showing severe shrinkage and porosity

Fig. 9 CT images of a turbine blade. (a) Residual core material from the casting process. (b) Scarfing caused by

near-tangential drilling of nearby walls

Dimensional Measurements. Because of the density sensitivity of the CT data and the averaging of the density values within a measured voxel, dimensional measurements can be made with better precision than the resolution of the image. The use of computed tomography for wall thickness gaging has advantages over other gaging techniques in that the measurements are not operator dependent, and precise information can be obtained from regions with internal walls and sharp curvatures.

Figure 10 shows a typical CT image of a turbine blade with the measured wall thickness information displayed. In this case, the wall thicknesses were measured with automated software, which makes many measurements along each wall segment (between ribs), marks the location of the thinnest portion, and posts the measured data in a table. The quantitative data can also be passed to a statistical software package for process control analysis. Applications are being pursued for using this dimensional information for subsequent machining operations, such as adjusting power levels for laser drilling. The ability to provide spatially specific structure and density information also opens up the opportunity to obtain three-dimensional data representations (Fig. 11) of physical components for computer-aided design documentation and computer-aided engineering analysis.

Fig. 10 Cross-sectional CT image through a turbine blade with wall thickness measurement locations and values determined with automated software

Fig. 11 Three-dimensional surface image of a turbine blade generated from CT data

Engineering Ceramics and Powder Metallurgy Products. The sensitivity of computed tomography to density differences of a fraction of 1% can be applied to a number of material characterization problems. Materials that vary in density or composition because of the fabrication process may benefit from this capability. Injection-molded powder metal components have been scanned with the potential of better density characterization and process control in the green state to produce an improved sintered product. The computed tomography of advanced ceramic materials is also increasing, especially for high-stress and complex-shaped components (Ref 12, 30).

Assembled Structures. In general, the advantages of computed tomography over alternative inspection methods increase with the complexity of the structure. The ability of computed tomography to image the components in an assembly does not reduce the need for component inspection prior to assembly. This ability can be a valuable tool, however, when quality questions arise regarding the assembled product. Computed tomography can also be used to verify proper assembly or help evaluate damage or distortion in components caused by the fabrication process.

Examples and potential applications for computed tomography cover a wide range. They include the evaluation of composite spars in helicopter rotor blades, detonators and arming devices, thermal batteries, and a variety of electronic assemblies. The major limitation is the capacity of the system and economic considerations, especially for large production volume items. Computed tomography can provide worthwhile capabilities even for low-cost, high-volume components by assisting engineering development and problem solving.

Industrial Computed Tomography

Michael J. Dennis, General Electric Company, NDE Systems and Services

CT System Design and Equipment

Computed tomography systems are relatively complex compared to some of the other NDE imaging systems. The production of high-quality CT images requires a stable radiation source, a precise mechanical manipulator, a sensitive x-ray detector system with high accuracy and a wide dynamic range, considerable computing power (usually with high-speed array processors), and radiation shielding for personnel safety. Consequently, the capital costs for industrial computed tomography systems tend to be well above those of most routine inspection systems.

The basic functional block diagram of an x-ray CT system is illustrated in Fig. 12. The major components include:

- A precision mechanical manipulator for scanning the testpiece with a radiation source and detector array. Several different scanning geometries are used to acquire the ordered set of transmission data (see the section "CT Scanning Geometries" in this article). The mechanical subsystem may also include

automated parts handling for loading and unloading the inspection station (Fig. 13)

- Radiation shielding for the safe use of the radiation source. The high-energy radiation sources used in industrial CT systems are typically shielded by placing the radiation source detectors in a room with shielded walls. Self-contained, shielded cabinet systems (Fig. 13) are often used for industrial systems with x-ray sources operating below 500 kV
- A radiation source, such as an isotopic gamma source, an x-ray system, or a linear accelerator. The radiation sources used in industrial CT systems are similar to the x-ray and γ -ray sources used in industrial radiography. These radiation sources are discussed in the article "Radiographic Inspection" in this Volume
- detector arrays for measuring the transmitted radiation. Industrial CT systems primarily use either gas ionization detectors or scintillation detectors
- A data acquisition system for converting the measured signal into a digital number and transmitting the data to the computer system
- A computer with appropriate software for controlling the data acquisition and reconstructing the cross-sectional image from the measured data
- A display system for displaying the cross-sectional image

Fig. 12 Functional block diagram of a typical CT system

Fig. 13 Automated industrial computed tomography system for the production inspection of small components. Parts-loading conveyor and cabinetized x-ray system are included in this setup.

In addition to these individual parts of a CT system, the overall capabilities of the total system are also important. The key capabilities of a CT system are:

- The ability to handle the range of components to be inspected
- The throughput or rate at which the components can be tested
- The ability to provide sufficient image quality for the specified inspection task by considering the selectable operational parameters of CT systems that affect image quality

CT Scanning Geometries

The CT scanning geometry is the approach used to acquire the necessary transmission data. In general, many closely spaced transmission measurements from a number of angles are needed. Four types of CT scanning geometries are shown in Fig. 14. Much of the historical progression of the data acquisition techniques has been driven by the need for improvements in data acquisition speed for medical imaging. In medical CT systems, the radiation source and detector are moved, not the patient. Industrial CT systems, however, often manipulate the component; this can simplify the mechanical mechanism and help maintain precise source-detector alignment and positioning. In either case, the relative positions of the object to the measured ray paths are equivalent. Some of the nomenclature derived from medical computed tomography does not readily accommodate some of the manipulator configurations that are practical in industrial imaging.

Fig. 14 Basic CT scanning geometries. (a) Single-detector translate-rotate, first-generation system. (b) Multidetector translate-rotate, second-generation system. (c) Rotate-only (rotate-rotate), third generation system. (d) Stationary-detector rotate-only, fourth-generation system. In medical systems, the source and detector are manipulated instead of the object.

Single-Detector Translate-Rotate Systems. The first commercial medical CT scanner developed by EMI, Ltd., uses a single detector to measure all of the data for a cross section. The x-ray source and detector are mounted on parallel tracks on a rotating gantry (Fig. 14a). The source and detector linearly traverse past the specimen and make a series of x-ray transmission measurements (240 measurements for a 160×160 image array). These measurements correspond to the transmitted intensity through the object along a series of parallel rays. The source-detector mechanics are rotated by 1° , and another linear traverse is made. This provides another set of parallel rays, but at a different angle through the object. This process is repeated until data are obtained over a full 180° rotation of the source-detector system.

The original EMI scanner uses two detectors to collect data for two adjacent slices simultaneously; it is relatively slow, with nearly a 5-min scan time to produce a low-resolution image. Despite its limitations, this system was a significant break-through for diagnostic medicine.

Single-detector translate-rotate CT systems are sometimes referred to as first-generation systems. The use of the generation nomenclature was originated by medical manufacturers to emphasize the newness of their designs and is sometimes used as a matter of convenience to describe the operation of a system. Current commercial systems do not use the single-detector approach, because of its limited throughput. The simplicity of this approach, however, makes it suitable for applications in basic research.

Multidetector Translate-Rotate Systems. To improve the data acquisition speed, multiple detectors can be used to make a number of simultaneous transmission measurements. The second-generation or multidetector translate-rotate systems use a series of coarsely spaced detectors to acquire x-ray transmission profiles from a number of angles simultaneously (Fig. 14b). The data measurements are still acquired during the translation motion, but the system makes a much larger rotational increment. The distance translated needs to be somewhat longer than that for a single detector system in order to have all source-detector rays pass over the entire object width, but fewer translations are needed to collect a full set of data. The mechanical system of a second-generation CT scanning geometry for industrial applications may range from a design for small components (Fig. 15) to a design for large castings (Fig. 16).

Fig. 15 CT and DR scanner designed for the nondestructive testing and dimensional analysis of a variety of parts up to 300 mm (12 in.) in diameter and 600 mm (24 in.) in length

Fig. 16 Industrial computed tomography system x-ray cell for the inspection of large fabricated components and castings with multiaxis parts manipulator

Rotate-Only Systems. Further improvement in data acquisition speed can be achieved by using a broad fan beam of radiation spanning the entire width of the object, eliminating the translation motion entirely. The fast scanning speed of rotate-only systems is important in medical imaging to minimize patient motion during the scan and for high patient throughput. Nearly all current medical scanners are rotate-only systems, with some of these systems making over 1 million transmission measurements for a complete scan in less than 2 s.

There are two basic configurations of rotate-only systems. Third-generation or rotate-rotate systems use many (sometimes over 1000) closely spaced detector elements that are fixed relative to the x-ray beam (Fig. 14c). The source-detector combination may rotate together around the specimen, as in medical scanners (hence the term rotate-rotate). In industrial systems, the object can rotate in order to obtain data from all angles. The reconstruction process for these systems is slightly different than for the other configurations because a transmission profile or view corresponds with a set of rays in the shape of a fan. The use of the term rotate-only in this article will refer to third-generation systems.

Fourth-generation or stationary-detector rotate-only systems have a stationary ring of detectors encircling the specimen, with the x-ray source rotating around the specimen (Fig. 14d). The x-ray fan beam exposes only a portion of the detectors at any moment in time. The data are usually regrouped into fan beam sets, with the detector at the apex of the fan, or into an equivalent parallel ray set. This configuration is generally less flexible, cannot utilize the ability to manipulate the object, and is normally not found in systems designed for industrial use. Fourth-generation geometries require less stringent detector element matching by a factor of 100 or so and are less susceptible to normalization and circular artifacts.

Operational Differences and Variations. Each of the CT scanning geometries has its advantages and limitations. The different approaches each have certain data acquisition parameters that tend to be fixed and others that are readily adjustable.

One of the major factors in determining image resolution is the spacing between the measured transmitted rays. (Other factors include source size, source-object and object-detector distances, detector aperture, and the reconstruction algorithm.) The resolution at the center of the image field and in the radial direction at the periphery is highly dependent on the ray spacing in a transmission profile. This ray spacing can be easily adjusted in translate-rotate systems by adjusting the linear distance moved between measurements during translation.

On rotate-only (third-generation) systems, this ray spacing is fixed by the spacing of the detector elements. Consequently, these systems use a densely packed detector array, with element spacings well below 1 mm (0.040 in.). The ray spacing through the object can be improved by moving the object closer to the x-ray source or by acquiring interleaving data over multiple rotations with the detector array shifting a fraction of the detector spacing.

The circumferential resolution at the periphery of the image is dependent on the angular separation between views and the diameter of the image field. The ray spacing along the circumference or the number of angular views acquired is a readily adjusted parameter on the rotate-only systems.

This angular separation is fixed by the detector array spacing on multidetector translate-rotate systems. Some variation can be achieved by changing the source-detector spacing, or interleaved angular measurements can be obtained with small angular increments.

Multidetector translate-rotate systems can adjust for object size by changing the translation distance to the object diameter plus the width of the fan beam at the object. This tends to be inefficient for a wide fan beam system with small objects, but gives considerable flexibility for large objects.

Rotate-only systems have a field-of-view defined principally by the detector array size and the source-object and object-detector distances (object magnification). These systems can be used for larger fields-of-view by shifting the detector or object between rotations to cover a wider field. However, this rotate-shift-rotate approach still acquires fan beam data during the rotation motion, versus the parallel ray data collected during translation on a translate-rotate system.

Another difference is in acquiring data for DR mode imaging. The DR images are commonly used on CT systems to locate the areas in a component where the CT slices should be obtained or can be used for radiographic inspection of the component.

The high-resolution detector of the rotate-only systems normally requires a single z-axis translation to produce a high-quality DR image. For even higher resolution, interleaved data can be obtained by repeating the rotational scan with a shift of a fraction of the detector spacing. For large objects, a scan-shift-scan approach can be used.

Translate-rotate systems are typically less efficient at acquiring digital radiographic data if the wider detector spacing requires multiple scans with shifts to provide adequate interleaving data. If the detector field-of-view does not cover the full width of the object, the object can be translated and the sequence repeated.

Considerable flexibility can exist for various requirements. The mechanical packaging and implementation of the particular data acquisition system are the limiting factors with regard to the range of capabilities. The different acquisition approaches, however, can determine the efficiency of a system in acquiring appropriate data as well as the subsequent imaging throughput.

Radiation Sources

Computed tomography reconstructions can be performed with any set of measured data along lines through an object. This can include the use of ultrasound, neutrons, charged particle beams, nuclear tracer distributions (PET and SPECT imaging), or emitted radio-frequency emissions from nuclei (NMR imaging). In most practical industrial applications, however, x-ray or γ -ray radiation is used in computed tomography.

The three types of radiation sources typically used in industrial computed tomography are x-ray tubes, γ -ray sources, or a high-energy x-ray source such as a linear accelerator. Each of these sources has advantages and disadvantages. The two types of x-ray sources can provide a high-intensity beam, but they also produce a broad spectrum that complicates the quantitative analysis of the projection data. Gamma-ray sources have a narrow energy spectrum but tend to be of low intensity. Other factors include the size of the source and the energy of the beam.

The ideal radiation source would provide a high-intensity beam of x-ray photons at a single energy (or optimum spectral spread) emanating from a very small area with an energy capable of transmitting a reasonable fraction of the x-rays through the object.

Gamma-ray source are used in some industrial computed tomography systems. A major advantage of γ -ray sources is that the high-energy photons produced by a radioactive source are all at specific energies, while x-ray sources produce photons over a wide range of energies. Changes in the average energy transmitted through various thicknesses of material can cause inconsistencies in the measured data, resulting in errors in the reconstructed image.

The most significant disadvantage of γ -ray sources is the limited intensity or number of gamma photons produced per second. The intensity can be increased by using more radioactive material, but this requires a larger radioactive source, which adversely affects the spatial resolution of the system. Also, because the energy of a γ -ray source is dependent on the radioactive material, the effective energy cannot be readily changed for different imaging requirements.

X-Ray Sources. The number of high-energy photons included in the CT scan measurements is the primary factor affecting the statistical noise in the reconstructed CT image. To collect the maximum number of photons in the least amount of time, x-ray sources are generally used rather than radioactive γ -ray sources. For x-ray sources up to 500 kV in operating voltage, x-ray tubes are used. When higher-energy x-rays are needed to penetrate thick or dense testpieces, linear accelerators are often used.

The key characteristics of an x-ray source include the operating voltage range, the effective size of the focal spot, and the operating power level. These characteristics are important in both radiography and computed tomography (see the article "Radiographic Inspection" in this Volume). In computed tomography, however, the stability of the x-ray source is especially important. Voltage variations are particularly disruptive in that they change the effective energy of the x-ray beam and can cause image artifacts. Current variations are less of a problem because x-ray intensity can be monitored by reference detectors.

X-ray collimators are radiation shields with open apertures that shape the x-ray beam striking the object and the detector. For CT systems, the radiation field is typically a thin fan beam wide enough to cover the linear detector array. A collimator (Fig. 1a) is located between the x-ray source and the object to shape the beam; normally, a second collimator is also placed between the object and the detector array to further define the object volume being sampled. One or both of the x-ray collimators may have an adjustable slot spacing to permit operator selection of the slice thickness.

One of the benefits of using a thin fan beam of radiation for CT and DR imaging is that most of the radiation scattered by the object will miss the detector array and not be measured. This improves the quality of the measured data over that obtained by large-field radiography.

Systems that use coarsely spaced detectors, such as multidetector translate-rotate systems, may also have detector aperture width collimators. These collimators reduce the effective size of the detector element, thus improving the transmission data resolution.

X-Ray Detectors

Detector Characteristics. The ability to measure the transmitted x-ray intensity efficiently and precisely is critical to x-ray CT imaging. The features of the detector that are important to imaging performance include efficiency, size, linearity, stability, response time, dynamic range, and energy range of effectiveness.

Detector efficiency is a quantitative measure of the effectiveness of the detector in intercepting, capturing, and converting the energy of the x-ray photons into a measurable signal. This efficiency is a factor in the image quality for a given x-ray source output, or the exposure time required to collect a sufficient amount of radiation. The three components of overall detector efficiency are described below.

The geometrical efficiency is the fraction of the transmitted beam passing through the measured slice volume that is incident on the active detectors. It is equal to the active detector element width in the plane of the slice divided by the center-to-center spacing between detector elements. The collection efficiency is the fraction of the energy incident on an active detector area that is absorbed in the detector. It is dependent on the atomic number and density of the detector material and on the size and depth of the detector. Lack of absorption occurs because of x-ray photons passing through the

detector without interacting or because of interactions in which some of the energy is lost due to scatter or characteristic x-ray emissions from the detector material. Conversion efficiency is the fraction of absorbed energy that is converted into a measurable signal.

Detector size consists of both the detector element width and height. The detector height determines the maximum slice thickness that can be measured. Increasing the slice thickness increases the collected x-ray intensity, thus reducing the image noise, but decreases z-axis (interplane) resolution and may increase partial volume blurring and partial volume artifacts. The measured slice thickness is adjusted by the slice thickness collimators to be less than the detector height.

The detector element width is a factor in determining the resolution of the CT image. On some CT systems, particularly the multidetector translate-rotate systems, the detector aperture width can also be adjustable with a collimator. This offers higher potential resolution with a lower geometrical efficiency.

Detector Consistency. Detector linearity is the ability to produce a signal that is proportional to the incident x-ray intensity over a wide range of intensities. Detector stability concerns the ability to produce a consistent response to a signal without drifting over time. Channel-to-channel uniformity relates to the consistency between the detector elements in their signal response, noise, aperture size, and other characteristics. These parameters are important for CT detector selection to produce the consistent data set required for image reconstruction. For reproducible characteristics, some degree of inconsistency may be correctable by computer processing of the measured data.

The detector response time is the effective time for the signal to settle and not be significantly influenced by prior incident intensities. The response time is a critical factor in determining how rapidly independent samples can be collected and the quality of the data. Some CT systems interrogate each detector at rates up to 10,000 times per second.

Dynamic range is the range of intensities over which accurate measurement can be made. It is usually specified as a ratio of the maximum signal output to the minimum output. The minimum signal output is limited by the electronic noise of the detector and its electronics. The level of electronic noise determines how finely the signal can be effectively sampled for processing by the computer.

Gas ionization detectors consist of an ionization chamber with a positive and negative electrode (Fig. 17). When radiation interacts with the gas inside the detector, the effect is to knock orbital electrons out of atoms, thus ionizing these atoms. The freed electrons in this gas are pulled to the positive electrode, and the positively charged atoms (anions) are pulled to the negative electrode. This principle is used in basic radiation survey meters, which use an ionization chamber to measure the amount of ionization occurring within a volume of air or gas.

Fig. 17 Typical configuration of a xenon gas ionization detector

Gas ionization detectors have been shown to be particularly effective in rotate-only CT scanners. Rotate-only systems require a closely spaced detector array with good detector uniformity to provide the finely sampled projection data for image reconstruction. These systems may contain well over 1000 individual detector elements in a contiguous array.

Ion chamber detectors define the individual array elements by the placement of the collecting electrodes of each detector element. Medical CT systems arrange the collecting electrodes between the detector elements, with a typical detector spacing of 1.2 mm (0.05 in.). Higher-resolution industrial detectors place the discrete electrodes above and below the x-ray fan beam, with typical detector spacings of 0.25 mm (0.01 in.). The spread of the resolution response function for tightly spaced detector systems, such as high-resolution ionization detectors, may be greater than the physical detector spacing because a small percentage of the intensity incident on a detector

element may scatter into adjacent detector elements, contributing to crosstalk between detectors.

Because of the high packing density, with little or no gap between active detector elements, the geometrical efficiency of gas ionization detector arrays is very good. Because a gas is used to stop the x-ray beam, the collection efficiency is typically lower than a high-density solid detector material of the same dimensions. The conversion efficiency of ionization detectors is very good in that few of the ions produced by the radiation are lost due to recombination before reaching the collecting electrode.

To improve the efficiency of the detector at stopping and measuring the ionizing radiation, a high atomic number gas at high pressure is used. The entire detector array is contained in a single pressure vessel that provides a common gas mixture and pressure for all detector elements and aids in producing a uniform detector response. Xenon, an inert gas, is used because of its high atomic number ($Z = 54$). High pressures are used that can increase the physical density of the gas up to 1.5 g/cm^3 (0.9 oz/in.^3).

Xenon ionization detectors provide high linearity over a wide range of x-ray intensities and have a reasonably fast response time associated with the travel time of the ions in the electric field of the chamber. Of particular benefit for third-generation rotate-only scanners is that xenon detectors are highly stable and do not exhibit radiation damage effects or other long-time-constant exposure effects that may distort the measured data.

Scintillation detectors, which have been used for many years to measure radionuclide emissions, are used in both translate-rotate and rotate-only CT systems. The two basic designs are shown in Fig. 18 and 19. The most preferred and widely used design in CT systems is the scintillation crystal-photodiode detector system (Fig. 18).

Fig. 18 Configuration for a scintillation crystal-photodiode detector

Fig. 19 Configuration for a scintillation crystal-photomultiplier tube detector

Scintillators. As with the gas ionization detectors, the x-ray radiation causes electrons in the atoms in the absorbing material to be excited or ejected from the atom. These electrons rapidly recombine with the atoms and return to their ground-state configuration, emitting a flash of visible light photons in the process. The term scintilla means spark or flash. Scintillation detectors typically use relatively large transparent crystals. The scintillator is encased in a light-reflective coating and is optically coupled to a sensitive light detector, such as a photomultiplier tube (PMT) (Fig. 19) or photodiode (Fig. 18).

Sodium iodide doped with thallium [NaI(Tl)] coupled to a photomultiplier tube is a standard scintillation detector used for nuclear radiation measurements. This type of detector was used on the original EMI medical scanner. However, new scintillating materials have resulted in improved performance for certain detector characteristics. The scintillation materials of choice are cadmium tungstate (CdWO_4) and bismuth germanate (BGO). The properties of the material are important to the efficiency and speed of the detector and its ability to provide accurate data. Table 3 lists some of these materials along with some of their key properties.

Table 3 Scintillator materials

Material	Decay constant, μs	Afterglow, % at 3 ms	Index of refraction	Density, g/cm^3	Conversion efficiency, % (versus NaI)
NaI(Tl)	0.23	0.5-5	1.85	3.67	100
CsI(Tl)	1.0	0.5-5	1.8	4.51	45
BGO	0.3	0.005	2.15	7.13	8
CaWO_4	0.5-20	1-5	1.92	6.12	50
CdWO_4	0.5-20	0.0005	2.2	7.90	65

The relatively high density and effective atomic number are key attributes of many scintillator materials, providing a highly effective ability to stop and absorb the x-ray radiation. The scintillation conversion efficiency, or fraction of x-ray energy converted to light, is about 15% for NaI(Tl). Table 3 lists the conversion efficiencies relative to sodium iodide with a standard light detector. The efficiency of the scintillator in producing light is important in that some of this light is lost by absorption in the scintillator, reflective walls, and optical coupling material. A high index of refraction increases the difficulty of optically coupling the scintillator.

The principal decay constant (time for the signal to decay to 37% of the maximum) is also listed in Table 3. Other lower-intensity but longer-duration decay constants may also exist. Long afterglow decay constants (from 1 to 100 s) in sodium iodide are one of its significant deficiencies for high-speed data acquisition. In addition to afterglow, the scintillator materials may also exhibit temporary radiation damage, such as reduced optical transparency, which also has an associated time constant for repair. The effect of prior radiation exposure on the measured signal is especially important when a wide range of intensities are to be measured by the detector. Careful selection and characterization of the scintillation detector material are necessary for high-speed CT data acquisition.

Photomultiplier Tube. The light detector is another important element in scintillation detector systems. Early systems utilized PMT optical sensors (Fig. 19). A photomultiplier tube is a vacuum tube with a photocathode that produces free electrons when struck by light. These electrons are accelerated and strike a positive electrode (dynode) that releases additional free electrons. A series of dynodes is used to obtain very high levels of amplification with low back-ground noise. For use on CT systems with high x-ray intensities, the photomultiplier tube is used to produce a signal current proportional to the rate at which x-ray energy is absorbed in the scintillator.

Scintillation crystal-photodiode array detectors have important advantages over photomultiplier tubes in CT applications. Although photomultiplier tubes are relatively efficient, they are subject to drifts in gain and are relatively bulky. Crystals with photodiodes are more stable and permit the use of small, tightly packed detector arrays. Therefore, photodiodes are commonly used as the optical sensor for CT scintillation detectors. Photodiodes produce a small current when light strikes the semiconductor junction. This current is then amplified by a low-noise current-to-voltage converter to produce the measured signal.

Very high resolution detector systems have been fabricated by coupling very thin slabs of scintillation material to high-resolution photodiode arrays. These photodiode arrays may have 40 or more individual photodiodes per millimeter on a single chip. Detectors with very small, tightly packed scintillation crystals may be particularly appropriate for the materials evaluation of small samples at low x-ray energies.

Quantum Noise (Mottle) and the Detective Quantum Efficiency. The beam intensity being measured consists of a finite number of photons. Even with an ideal detector, repeated measurement will contain a certain degree of random variation, or noise. The standard deviation of the number of photons detected per measurement is \sqrt{N} , where N is the average number of photons detected per measurement. Therefore, the signal-to-noise ratio (SNR) can be given by:

$$\text{SNR} = \frac{N}{\sqrt{N}} = \sqrt{N} \quad (\text{Eq 1})$$

Just as fast films that require less exposure tend to produce grainy images, the fewer the number of photons detected, the lower the signal-to-noise ratio. Because this type of noise is due to the measurement of a finite number of discrete particles, or quanta, it is referred to as quantum noise.

Because practical radiation detectors are imperfect devices, not all x-ray photons are absorbed in the detector. In gas ionization detectors, each photon absorbed produces a finite number of measured electrons with their own quantum statistics. In scintillation detectors, a finite number of light photons reach the light sensor, and a finite number of electrons flow in the sensor. Each of these steps has its own quantum statistics (that is, quantum noise). The detector electronics, particularly the initial amplifiers, introduce additional noise into the measured signal, which adds to the quantum noise.

The overall efficiency of the detector, including the noise added to the signal in the detection process, can be characterized by comparing its performance to that of an ideal detector. The detective quantum efficiency (DQE) of a detector is the ratio of the lower x-ray beam intensity needed with an ideal detector to the intensity incident on the actual detector for the same signal-to-noise ratio. If the only increase in noise versus an ideal detector is due to the absorption efficiency, that is, the fraction of photons absorbed in the detector, the DQE would equal the absorption efficiency.

Other losses of the signal occur in the detection process, and other sources of noise can be introduced into the signal to further reduce the signal-to-noise ratio for actual measurements. The result in the quality of the measured signal is effectively the same as detecting fewer photons. The DQE can be determined by comparing the measured signal-to-noise ratio to that calculated for an ideal detector as follows:

$$\text{DQE} = \frac{(\text{SNR}_{\text{detected}})^2}{(\text{SNR}_{\text{incident}})^2} \quad (\text{Eq 2})$$

The designers of CT detector systems strive to maximize overall detector efficiency while meeting the size, speed, stability, and other operational requirements of a practical CT system.

Data Acquisition System

The data acquisition system is the electronic interface between the detector system and the computer. It provides further amplification of the detector signals, multiplexes the signals from a series of detector channels, and converts these analog voltage or current signals to a binary number that is transmitted to the computer for processing.

Some of the factors key to this electronics package include low noise, high stability, ability to calibrate offset and gain variations, linearity, sensitivity, dynamic range, and sampling rate. The electronics of the data acquisition system should be well matched to the detector system to minimize degradations to the data accuracy and scanning performance.

The dynamic range of the detector system is characterized by the ratio of the maximum signal to the noise. The dynamic range of the data acquisition system is given by the range of numbers that can be transmitted to the computer, often specified by the number of bits per measurement. It is not uncommon for CT systems to have a dynamic range of 20 bits (2^{20}), or 1×10^6 to 1.

Although it is difficult to build practical analog-to-digital converters with a 20-bit dynamic range, this electronics problem has been solved in several different ways. One way is to use an autoranging or floating-point converter. In this case, a linear converter is preceded by an adjustable-gain amplifier. One of several ranges can be selected by changing the gain of the amplifier, usually by a factor of two. If an autoranging amplifier having four range settings corresponding to gains of 1, 2, 4, and 8 precedes a 16-bit linear converter, the overall dynamic range is 20 bits, while the sensitivity varies from 1 to 2^{16} for high intensities to 1 in 2^{20} for low intensities relative to the maximum measurable intensity.

Computer System

Computer systems vary considerably in architecture, with computational performance steadily increasing. The availability of practical minicomputer systems was the enabling technology for the development of computed tomography in the early 1970s. Computed tomography imaging has benefited from the computational improvements by permitting increasing amounts of transmission data to be measured to produce larger, more detailed image matrices with less processing time. High-speed computer systems are also enabling increasingly sophisticated data processing for image enhancement, alternate data presentations, and automated analysis.

Evaluating computer system performance parameters is difficult, especially with the use of distributed processing. It is common to have several processing systems controlled by a central processor or operating relatively independently in a network configuration. This distributed processing may include programmable controllers and numerical controllers for automated parts handling, manipulator control, and safety monitoring; specialized array processors for image reconstruction; image processor for image enhancement and analysis; and display processors for presentation.

Because computed tomography uses large amounts of data (millions of transmission measurements to produce an image containing up to several million image values) and because several billion mathematical operations are required for image reconstruction, high-speed array processors are used for image reconstruction. Array processors are very efficient devices for performing standard vector or array operations. The CT reconstruction technique commonly used also requires a backprojection operation in which the projection values are mapped back into the two-dimensional image matrix. Consequently, most CT systems contain specialized processors designed to perform this operation efficiently in addition to standard array operations.

Data handling and archiving can also become significant considerations because of the size of the data files. Optical disks can be beneficial for compact archiving as an alternative to magnetic tape. High-speed data networking can also provide improved utility in transferring data to alternate workstations for further review and processing.

Industrial Computed Tomography

Michael J. Dennis, General Electric Company, NDE Systems and Services

Image Quality

Flaw sensitivity and image quality are the two basic criteria for evaluating the ability of any imaging system to define sufficiently certain structures for a range of test object situations. Although image quality is a requirement in achieving adequate flaw sensitivity, the evaluation of flaw sensitivity can be ambiguous in relation to inspection task requirements. The analysis for the sensitivity of defined features in specific components can be quite complex and may involve probability-of-detection or relative-operating-curve analysis. These analyses are also dependent on the perception and skill of the interpreter and on the decision criteria, which may emphasize maximizing true positive or minimizing false negative indication detection.

To evaluate and monitor the image quality and performance of an imaging system, a number of simpler methods can be used to characterize the resolution, sensitivity, and accuracy of a system. The three basic factors affecting image quality and system performance are:

- Spatial resolution
- Image contrast
- Image artifacts

These three factors are discussed in the following sections.

Spatial Resolution

Spatial resolution is a measure of the ability of an imaging system to identify and distinguish small details. As in measuring the resolution of a radiographic system, an image of a regularly repeating high-contrast pattern is typically evaluated. The equivalent to a radiography line pair gage for computed tomography is a bar pattern resolution test phantom.

Resolution Test Patterns. A CT resolution bar phantom consists of a stack of alternating high- and low-density layers of decreasing thickness. This phantom is scanned such that the layers are perpendicular to the slice plane. The resultant CT image displays a bar pattern, and the minimum resolvable bar size (layer thickness) is determined (Fig. 20). This measure can be reported as the bar size or as line pairs per millimeter.

Fig. 20 CT image on a medical CT system of a resolution bar phantom. The center pattern has 0.5 mm (0.020 in.) bars on 1.0 mm (0.040 in.) spacings.

Alternatively, resolution hole patterns can be used. This type of phantom is a uniform block of material (usually cylindrical) containing a series of drill holes. The holes are often arranged in rows, with the hole spacings twice the hole diameter. Hole patterns can also be placed in test specimens to demonstrate resolution in the materials to be scanned. As with the bar pattern, the minimum resolvable hole size is determined as a measure of the resolution.

Some differences may exist in the measured results for a system with the different test patterns described. Bar patterns will generally indicate a higher-resolution performance than holes, probably because of the improved perceptibility of the larger structures.

If the system resolution is approaching the display resolution for an image, the relative position of the test structures to the voxels may affect the results. This can be avoided by orienting the test pattern at a 45° angle to the pixel row pattern of the displayed image.

Point Spread Function (PSF). The image produced by a system is a blurred reproduction of the actual object distribution. A more complex way of characterizing resolution and ability to reproduce the object structure is by measuring the degree of image blurring or the PSF of the system. The PSF is the image response to a very small or

pointlike feature. This measurement can be made on a CT system by imaging a fine wire oriented perpendicular to the slice plane (additional information on the point spread function is available in the section "Convolutions and Filters" in Appendix 1 in this article).

If the pixel spacing is close to the resolution of the system, the extent of the PSF may extend for only a few pixels and be poorly characterized. The PSF can also be determined from measurements of the line spread function (LSF) or edge response function (Ref 31). The LSF is a normalized plot of the image across a line, such as a very thin sheet of metal oriented perpendicular to the slice plane. The edge response function is the plot of the image across a low-density to high-density boundary.

It is helpful in making LSF and edge response function measurements to orient the line or edge slightly out of alignment with the columns of displayed pixels. By determining the relative position of data from several rows, one can obtain a finer sampling of these functions. These functions can be partially characterized as a single parameter by reporting the full width at half the maximum value of the spread function.

Modulation Transfer Function (MTF). Fourier theory states that a signal or an object can be described by a series of sinusoidal functions. The MTF is a plot of the ability of the imaging system to transfer a sinusoidal signal versus the frequency of that signal. The MTF for an imaging system is equivalent to evaluating the frequency response of an audio system, except that the MTF is in terms of spatial frequency (cycles per unit distance).

The bar resolution test measurements provide an approximation to the MTF values. Thick bars show maximum contrast between the high- and low-density materials, corresponding to the difference in linear attenuation coefficient of the materials. As the bars become thinner, the overlap of the blurring at the edges tends to reduce the apparent CT number of the high-density material and raise the values for the low-density material. The contrast or difference in CT number diminishes and can be reported as a fraction of the large bar contrast.

The MTF is similar to a plot of contrast versus cycles per millimeter, except that it is for an idealized test object with a sinusoidal density variation. Because fabricating such a sinusoidal distribution is impractical, the MTF is normally determined by taking the normalized Fourier transform of a measured PSF. In reporting specific values from the MTF function, the spatial frequency (line pairs per millimeter) at which the contrast transfer falls below a specified value (such as 50, 20, or 10%) is sometimes given.

Factors Affecting Resolution. One of the major factors in determining resolution is the spacing between the measured transmitted rays. The resolution at the center of the image field and in the radial direction at the periphery is highly dependent on the ray spacing in a transmission profile. This ray spacing can be easily adjusted in translate-rotate systems by adjusting the linear distance moved between measurements during translation.

Other factors that affect resolution include source size, degree of geometric magnification, detector aperture, and the reconstruction algorithm. The resulting resolution of the reconstructed image may also be limited by the display system.

The measured spatial information is dependent on the sample spacing of the data and on the degree of blurring that occurs in these data. Practical measurements are made with radiation sources of a finite size and a detector with a definable aperture width. A single transmission measurement is therefore a type of average over a ray of some width. This ray profile is dependent on the size and shape of the focal spot, the width of the detector aperture, and the relative position between the source and the detector. An approximation to the effective beam width, known as the effective aperture size, is given by (Ref 32):

$$a_{\text{eff}} = \frac{a^2}{M^2} + \frac{s^2}{[M/(M-1)]^2} \quad (\text{Eq 3})$$

where a is the detector aperture and s is the width of the x-ray focal spot. The variable, M , is the magnification factor given by:

$$M = \frac{\text{SDD}}{\text{SOD}} \quad (\text{Eq 4})$$

where SDD is the source-detector distance and SOD is the source-object distance. If the magnification factor is close to 1, as in contact film radiography, the detector resolution is the critical factor. As the magnification increases, a greater burden is placed on having a small x-ray source in order to produce a high-resolution image.

If the sampled data are at a finer spacing than the effective aperture, deconvolution processing of the measured data can reduce the effective aperture somewhat, but the result will be an increase in noise in the data (see the section "Convolutions and Filters" in Appendix 1 of this article). Sample spacings through the object below one-half the effective aperture, however, have little benefit because of the lack of appropriately detailed (high-frequency) information in the measurements (Ref 31).

The sample spacing can also be a limiting factor to the resolution of the system. The Nyquist sampling theorem states that sampling frequency must be at least twice the maximum spatial frequency of the structure being measured. This becomes clear if one thinks of making sampled measurements across the bar resolution pattern. To define the one line-pair per millimeter bars, two samples per millimeter are required--one for the high-density bar and the other for the low-density space between bars.

Given an adequately small effective aperture, the sample spacing within a view is the limiting resolution factor in the radial dimension from the center of the image. However, the circumferential resolution, perpendicular to the radius, is primarily associated with the angular separation between views. This can present particular difficulties near the periphery of the object, where the angular separation of the data corresponds to an increasingly large linear distance along the circumference. The larger the diameter of the object, the larger the number of angular views required to maintain a given circumferential resolution at the edges.

The measured transmission values are processed by a reconstruction algorithm to obtain the image, with the filtered backprojection technique being the common method used. The filter function can be modified or the image postprocessed to yield a certain degree of smoothing in the image in order to minimize the image noise. This smoothing is obviously an additional factor affecting the system resolution.

Also part of the reconstruction process is the backprojection of the projection data into the image matrix. The rays corresponding to the measured data generally do not pass through the center of each affected pixel; therefore, interpolation between measured values is required. The method of interpolation can also affect the image resolution and noise.

The reconstructed image is a two-dimensional array of data with a defined pixel spacing in terms of object dimensions. The Nyquist sampling theorem also applies in this case, and details smaller than the pixel spacing cannot be accurately defined. The pixel spacing can be a significant limitation where a large object is viewed in a single image. The quality of the display system or recording media can also further degrade the resolution contained in the resultant image.

Many factors can affect the final resolution of the images. Appropriate system design and scan parameter selection are required for optimizing the image quality for a given task.

Image Contrast

As with other imaging systems, the amount of contrast on a CT image is governed by object contrast, the contrast resolution of the detector-readout system, and the size of a discontinuity with respect to the spatial resolution of the system. The following sections describe these factors affecting image contrast, along with the use of contrast-detail-dose diagrams for gaging these interrelationships in a particular scanning situation.

Object contrast refers to the contrast generated by variations in the attenuation of the radiation propagating through the testpiece. Object contrast is a function of the relative differences in the linear attenuation coefficients and is affected by the x-ray energy and the composition and density of the materials.

In order for a feature to be detected or identified, it must have a displayed density noticeably different from that of the surrounding material. Computed tomography images are a scaled display of the linear attenuation coefficients of the materials within the specimen. The relative contrast between a feature and the surrounding background material is the normalized difference between the two linear attenuation coefficients, that is:

$$\text{Contrast (\%)} = \frac{|\mu - \mu_b|}{\mu_{\text{ref}}} \cdot 100\% \quad (\text{Eq 5})$$

where μ and μ_b are the linear attenuation coefficient of the feature of interest and the background material, respectively. The reference coefficient, μ_{ref} , is normally that of the background material, but the maximum coefficient of the two materials can be used, especially if the background material is air or has a very low relative value.

The linear attenuation coefficient values are a function of the physical density of the material, the composition or effective atomic number of the material, and the effective energy of the x-ray beam. The effect of the atomic number on the linear attenuation coefficient is especially important at lower energies (sub-MeV) and for high atomic number materials; in these cases, photo-electric absorption interactions are a significant factor in the overall attenuation. This effect of atomic number can yield a much larger relative contrast at the low energies relative to high-energy scanning; however, sufficient beam energy is required for penetrating the full thickness of the object and collecting an adequate photon signal.

At very high energies, where Compton scattering interactions overwhelmingly dominate, atomic number has relatively little effect. Under these conditions, the linear attenuation coefficient tends to be proportional to the electron density of the material, which corresponds quite closely to the physical density of the material. For situations in which the composition of the material is uniform, the linear attenuation coefficient is directly proportional to the physical density of the material.

Size and Partial Volume Effect. In addition to the true object contrast, other factors also influence the measured and displayed contrast between structures. When the voxel or sampled volume corresponding to a pixel contains two or more separate structures, the resulting pixel value is a volume average of the structures. This is one of the causes for the rounded profile or intermediate CT numbers found along boundaries. The edge pixels correspond to a combination of the high- and low-density materials.

With small features, such as subresolution inclusions or cracks, only part of the voxel is occupied by this structure (Fig. 21). In these cases, the feature may be detectable, but the measured or apparent contrast is less than the difference between the two materials. The smaller the feature, the less the imaged contrast. For situations in which the CT number values are known for the two materials, this partial volume effect can be used to estimate the size of the feature or to measure structural dimensions with subresolution accuracy.

Fig. 21 Schematic of structures partially filling a sampled voxel. The structures yield a measured CT value that correspond to a volume average of the two materials.

The resolution characteristics of the imaging system and the degree of blurring in the image also reduce the apparent contrast difference for small structures. Where the ideal image of a small structure would be a single pixel with a CT number corresponding to the average linear attenuation coefficient within the voxel, the image blurring spreads this measured signal over a large area. This can be thought of as an extension of the partial volume effect, in which the

volume corresponding to a pixel is the three-dimensional sensitivity distribution of object locations affecting the pixel value.

Noise and Contrast Sensitivity. The contrast sensitivity of the imaging system is defined by the signal-to-noise ratio and is affected by unwanted random variations in the measured data and the reconstructed image. Image noise is a primary limiting factor in distinguishing low-contrast structures and in detecting high-contrast subresolution features that appear in the image as low-contrast structures. The random uncertainty of the CT numbers causes subtle features to be lost in the texture of the noise.

A primary contributor to image noise is the quantum noise (or mottle) in the measured data due to measurement of a finite number of x-ray photons (Eq 1). Additional sources of noise are the data acquisition system electronics and roundoff errors in the computer processing.

Measurement of Noise. The typical measurement of noise is the standard deviation of the CT number values over an area of many pixels. The CT number standard deviation is commonly measured near the center of the cylindrical test object and may vary with radial position. Because the results are dependent on the quantity of x-rays transmitted through the object, the size and material of the test object should be specified. The noise is often reported as a percentage of the CT number difference between the test object and air.

A more complete method of characterizing the noise is to determine the noise power spectrum of the system over a series of images. The noise power spectrum defines the noise content in the image versus spatial frequency. As a consequence of the filtering operation of the reconstruction process, CT images predominantly contain high-frequency noise.

Factors Affecting Noise. Because x-ray photon statistics (that is, quantum noise) is a major contributor to the noise, factors that increase the number of photons detected tend to reduce the noise (Eq 1). The factors affecting the number of detected photons are:

- The intensity of the radiation source
- The source-to-detector distance
- The attenuation of radiation passing through the testpiece (which in turn is a function of the thickness and material of the testpiece and the energy of the incident radiation)
- The overall detection efficiency of the detector

The overall efficiency with which the useful x-ray beam is captured and measured depends on the geometrical, absorption, and conversion efficiencies of the detector. The geometrical efficiency increases with the number of detectors and the detector aperture width. The absorption and conversion efficiencies depend on the detector design, including the size and material composition of the detector. The number of photons detected is also directly proportional to the scanned slice thickness.

In addition to the transmitted primary photons, which constitute the x-ray signal, a certain amount of the detected radiation is scattered radiation. This scattered radiation reduces contrast by creating a field of background noise. Reduction of scatter, by tight collimation or increasing the object-to-detector distance, reduces this contribution to noise.

The reconstruction process also affects the resultant image noise. For ideal noise-less data, the shape of the reconstruction filter is a high-pass ramp function, which amplifies the high-frequency noise. Because the signal content at these high frequencies may be low due to other factors (such as the effective detector aperture), image quality can be improved for certain imaging tasks by windowing this ramp function and by reducing the amplification of the high-frequency signal and noise. This is effectively the same as smoothing the final image. A CT system may have selectable filters or algorithms that provide variable degrees of smoothing.

The high-frequency content of the noise caused by the reconstruction filter is negatively correlated. This means that if one pixel has a large positive noise fluctuation, surrounding pixels are more likely to have a negative fluctuation. Because the image noise is negatively correlated, filter windowing or smoothing can be particularly advantageous in improving the detectability of low-contrast structures (Ref 33). For situations in which the resolution is limited by the reconstruction process and the effect of the effective aperture is small, the number of detected photons required to maintain a given signal-to-noise ratio is inversely proportional to the resolution cubed (Ref 34). Under these conditions, improving the

resolution by a factor of two has the same effect on the signal-to-noise ratio as increasing the number of photons detected by a factor of eight.

Other limitations in system implementation can also contribute to the noise. The high-sensitivity detector and data acquisition system electronics adds some electronic noise to the signal. The reconstruction process consists of a large number of computational operations, and the roundoff errors in these calculations can also contribute to image noise. In addition, noise included in reference measurements used to normalize the scan projection data adds to the noise of the reconstructed image.

Contrast-Detail-Dose (CDD) Diagram. The perception of a feature is dependent on the contrast between the feature and the background, the size of the feature, the noise in the image, and the display window settings used to view the image data. One method of gaging the range of structures that may be resolved is by determining the CDD characteristics for a particular scanning situation (Ref 35, 36).

The CDD diagram is a plot of the imaged percent contrast versus the diameter of resolvable cylindrical test structures. Figure 22 shows a CDD diagram for two similar systems with different detector spacings. Figure 22 also shows the effect of changing the object dose, or number of photons collected, on the ability to resolve features.

Fig. 22 CDD diagram for two similar CT systems. The resolvability is limited by system resolution for high-contrast objects and by noise for low-contrast structures.

For high-contrast structures, the ability to resolve the features has little dependence on the dose or image noise, but is dependent on the resolution characteristics of the system. System A, which resolves smaller-diameter features, has a smaller detector aperture and sample spacing than system B (Fig. 22).

As the contrast of the features decreases and the feature contrast approaches the noise variation in the image, larger structures are required in order to distinguish them from the surrounding noise (Ref 37, 38). With the low-contrast structures, the importance of the overall resolution capability of the system is reduced, and the level of noise in the image becomes more critical. The two systems in Fig. 22 have similar performance for low-contrast features, with the object dose and the level of noise in the image becoming the dominant factor.

System resolution can be measured for different contrast structures with a low-contrast detectability test phantom such as the one shown in Fig. 23. This image demonstrates the ability of computed tomography to display very low contrast, large-area structures. The measured results of these tests depend on factors that affect the structure contrast versus the noise, including the size and the material of the test phantom.

Fig. 23 CT image of low-contrast detectability test phantom

Image Artifacts

Artifacts are image features that do not correspond to physical structures in the object. All imaging techniques are subject to certain types of artifacts. Computed tomography imaging can be especially susceptible to artifacts because of its sensitivity to small object differences and because each image point is calculated from a large number of measurements (Ref 39).

The types of artifacts that may be produced and the factors causing them must be understood in order to prevent their interpretation as physical structures and to know how scan operating parameters can be adjusted to reduce or eliminate certain image artifacts. In general, the two major causes of CT image artifacts are the finite amount of data for generating the reconstructed image and the systemic errors in the CT process and hardware. Some of the factors that can cause the generation of artifacts include inaccuracies in the geometry, beam hardening, aliasing, and partial penetration (Ref 40, 41, 42).

Aliasing and Gibbs Phenomena. Because of the finite number of measurements, certain restrictions are placed on the resolvable feature size. A series of adjacent x-ray transmission measurements allows the characterization of object structures that are larger than this sample spacing. Coarse sampling of detailed features can create falsely characterized data. The effect of this undersampling of the data is termed aliasing, in which high-frequency structures mimic and are recorded as low-frequency data. This effect can cause image artifacts that appear as a series of coarsely spaced waves or herringbone-type patterns over sections of the image (Fig. 24).

Fig. 24 Illustration of undersampling of a distribution containing high-frequency information causing the false appearance of low-frequency information or aliasing

Computed tomography systems do not measure the transmission data for infinitely thin rays. The detector has an aperture of some finite thickness, and very fine structures within this broad ray tend to be smoothed out or eliminated from the signal before being measured. This effective smoothing of the data prior to sampling acts to limit the spatial frequency content prior to sampling and minimizes the potential for aliasing artifacts.

Aliasing can also occur as a result of the reconstruction process. If one attempts to reconstruct an image in which the pixel spacing is much greater than the finely sampled projection data, the high-frequency information in the projection data can cause aliasing artifacts in the image. This can be eliminated through appropriate selection of the reconstruction filter function to filter out or eliminate spatial frequencies higher than that contained in the reconstructed image matrix.

The Gibbs phenomenon is also a type of artifact associated with the limited spatial frequency response of the system. It is a consequence of a sharp frequency cutoff in the reconstruction filter function. This causes overshooting or oscillations along high-contrast boundaries. The range and spacing of these oscillations decrease as the cutoff frequency increases. This type of artifact can be minimized by windowing the reconstruction filter function such that it has a smooth roll-off, rather than a sharp cutoff, at the high frequencies.

View aliasing is a form of aliasing resulting from an insufficient number of angular views. This artifact is typically a radial streaking pattern that is apparent toward the outer edges of the image or emanates from a high-contrast structure within the cross-sectional slice. The number of angular views required is dependent on the diameter of the object, the circumferential resolution of the image, and the effective aperture width.

Partial Volume Artifacts. The partial volume effect is the volume averaging of the linear attenuation coefficients of multiple structures within a voxel. Because of the exponential nature of the x-ray attenuation, the actual averaging process can cause nonlinearities or inconsistencies in the measured projection data that produce streaking artifacts in the image.

In Eq 8, 9, and 10 in Appendix 1, the attenuation through a series of materials is shown as the exponential of the sum of individual material attenuation properties. This relationship is used to obtain the line integral of the linear attenuation coefficients of the object along a ray, called a projection value. With the finite size of the measured x-ray beam, if two materials are positioned such that part of the measured ray passes through one material and the other part of the ray passes through the other material, the attenuation equation is the sum of exponential terms rather than the exponential of a sum.

Situations in which only part of a measured ray passes through a structure include rays tangential to high-contrast boundaries and object structures that may penetrate only partially into the measured slice thickness (Fig. 21). If the two materials have considerably different attenuation coefficient values, this inconsistency in the measured data can become significant and cause streaks emanating along edges, from high-contrast features, or between high-contrast features. Artifacts can be particularly prevalent between multiple high-contrast features that only partially intersect the slice thickness.

Partial volume artifacts can be reduced by decreasing the effective ray size with thinner slice thickness and narrower effective aperture. Smoothing or windowing the reconstruction filter also reduces the sensitivity to these artifacts. Another

approach is to reduce the contrast of the boundaries by immersing or padding the object with a material having intermediate or similar attenuation values.

Beam Hardening. X-ray sources produce radiation with a range of photon energies up to the maximum energy of the electron beam producing the radiation. The lower-energy, or soft, photons tend to be less penetrating and are attenuated to a greater degree by an object than the higher-energy photons. Consequently, the effective energy of a beam passing through a thick object section is higher than that of a beam traversing a thin section. This preferential transmission of the higher-energy photons and the resulting increase in effective energy is referred to as beam hardening.

Changes in the effective energy of the x-ray beam due to the degree of attenuation in the object cause inconsistencies in the measured data (Ref 43). X-rays that pass through the center of a cylindrical object will have a higher effective energy than those traversing the periphery. This leads to a lower measured linear attenuation coefficient and lower CT number values in the center of the reconstructed image. This CT number shading artifact is referred to as cupping, corresponding to the shape of a plot of CT numbers across the object.

The effect of beam hardening can be reduced with several techniques. The original EMI scanner used a constant-length water bath that yielded a relatively uniform degree of attenuation from the center to the periphery. The addition of x-ray beam filtration reduces the soft x-rays and reduces the degree of beam hardening. Compensating or bow tie shaped x-ray filters are sometimes used in medical CT systems to increase the beam filtration toward the periphery and to have a smaller attenuation variation across a cylindrical-shaped object. Normalizing the data with a cylindrical object of similar size and material as the test object also reduces the effect of the beam hardening.

Beam hardening is often compensated for in the processing software. If the material being scanned is known, the measured transmission value can be empirically corrected. Difficulty occurs, however, when the object consists of several materials with widely varying effective atomic numbers. The extent of the beam hardening depends on the relative degree the attenuation is from the highly energy dependent and atomic number dependent photoelectric absorption versus the less energy dependent and atomic number independent Compton scattering process. Different materials have differing degrees of attenuation of the low-energy versus high-energy photons for a given overall level of attenuation.

Other processing techniques for minimizing beam hardening artifacts are sometimes used. If the object is composed of two specific materials that are readily identifiable in the image, an iterative beam hardening correction can be implemented (Ref 44). This approach identifies the distribution of the second material in the image and implements a correction of the projection data for an improved second reconstruction of the data. Dual energy techniques can also be used. These techniques use data obtained at multiple energies to determine the relative photoelectric and Compton attenuations and can produce images that are fully corrected for beam hardening.

Scatter Radiation. Detected scatter radiation produces a false detected signal that does not correspond to the transmitted intensity along the measured ray. The amount of scatter radiation detected is much lower than that encountered with large-area radiographs because of the thin fan beam normally used in computed tomography. The sensitivity of computed tomography, however, makes even the low levels of scatter a potential problem.

The scatter contribution across the detector array tends to be a slowly varying additive signal. The effect on the measured data is most significant for highly attenuated rays, in which the scatter signal is relatively large compared to the primary signal. The additional scattered photons measured make the materials along the measured ray appear less attenuating, which is the same effect caused by beam hardening.

The types of artifacts caused by scatter radiation are similar to and often associated with beam hardening. In addition to the cupping-type artifact, beam hardening and scatter can also cause broad, low CT number bands between high-density structures. The rays that pass through both of the high-density structures are highly attenuated, and the increase in effective energy and the scatter signal makes the materials along these rays appear to be less attenuating than is determined from other view angles.

Because of the similarities of the effect, the basic beam hardening correction often provides some degree of compensation for scatter. The amount of scatter radiation detected can be modeled, and specific scatter correction processing can be implemented. Fundamental dual energy processing, however, does not correct for the detected scatter radiation.

Control of Scattered Radiation. System design can also minimize the detected scatter radiation. A tightly collimated, thin x-ray beam minimizes the amount of scatter radiation produced. Increasing the distance between the

object and the detector decreases the fraction of the scatter radiation that is detected. The use of focused collimators or directionally sensitive detectors also reduces the amount of detected scatter radiation. Because the scatter radiation varies slowly with distance, special reference detectors outside of the primary radiation beam can be used to measure the level of the scatter signal.

Other Systemic Errors. A number of other systemic errors in data measurement can produce inconsistent data and can result in artifacts or degraded image quality. These inconsistencies may be in the measured signal or may be the result of poor characterization of the spatial position of the measured ray paths.

In medical CT imaging, patient motion is a major concern. If the object being scanned moves or changes configuration during data acquisition, the measured data set does not correspond to a specific object. In addition to image blurring, streaking from boundaries and high-density structures occurs. This is less of a problem with rigid structures in industrial imaging. However, objects undergoing dynamic changes relative to the scan time, as in a fluid flow study, or poorly fixtured components that wobble or vibrate during data acquisition can degrade the image quality.

Data are acquired along many ray paths, and the precise combination of this data produces the reconstructed image. Imprecise manipulator motions, geometric misalignment, or insufficiently characterized positioning can also cause blurring and image artifacts. An example is a series of tangential streaks forming a star pattern on translate-rotate systems that can be caused by misalignments between traverses.

Inconsistencies in the data measurements may be due to variations in x-ray source output, the detector, or the detector electronics. The x-ray tube output is normally measured by reference detectors, and the data are scaled appropriately. This is effective for tube current changes that do not alter the effective energy of the x-ray beam. Changes in the tube voltage, however, produce changes in both x-ray intensity and effective energy and are more difficult to correct. A highly stable x-ray generator with feedback control of the voltage is normally required.

Measurement errors may also be the result of nonlinear detector performance over its entire dynamic range, detector overranging, or differences between detector elements in a multidetector array. Detector overranging for a limited number of measurements typically produces well-defined streaks through the image. Third-generation, rotate-only CT systems in particular require a highly consistent detector array because uncharacterized variations between detectors cause concentric ring artifacts. Oscillating changes in the detected signal can also occur because of mechanical vibration of the detector or components within the detector or because of the pickup of electronic interference, especially at the line voltage frequency.

Special Features

The components that constitute a CT system often allow for additional flexibility and capabilities beyond providing the cross-sectional CT images. The x-ray source, detector, and manipulation system provide the ability to acquire conventional radiographic images. The acquisition of digital images along with the computer system facilitates the use of image processing and automated analysis. In addition, the availability of the cross-sectional data permits three-dimensional data processing, image generation, and analysis.

Digital Radiography. One of the limitations of CT inspection is that the CT image provides detailed information only over the limited volume of the cross-sectional slice. Full inspection of the entire volume of a component with computed tomography requires many slices, limiting the inspection throughput of the system. Therefore, CT equipment is often used in a DR mode during production operations, with the CT imaging mode used for specific critical areas or to obtain more detailed information on indications found in the DR image. Digital radiography capabilities and throughput can be significant operational considerations for the overall system usage.

Computed tomography systems generally provide a DR imaging mode, producing a two-dimensional radiographic image of the overall testpiece. The high-resolution detector of the rotate-only systems normally requires a single z -axis translation (Fig. 25) to produce a high-quality DR image. For even higher resolution, interleaved data can be obtained by repeating with a shift of a fraction of the detector spacing. For large objects, a scan-shift-scan approach can be used. The translate-rotate systems are typically less efficient at acquiring DR data because the wider detector spacing requires multiple scans, with shifts to provide adequate interleaving of data. If the width of the radiographic field does not cover the full width of the object, the object can be translated and the sequence repeated.

Fig. 25 Digital radiography mode. The component moves perpendicular to the fan beam, and the radiographic data are acquired line-by-line.

The capabilities and use of these DR images are generally the same as discussed for radiographic inspection. The method of data acquisition is different on the CT systems; the data are acquired as a sequence of lines or line segments. The use of a thin fan beam with a slit-scan data acquisition is a very effective method of reducing the relative amount of measured scatter radiation. This can significantly improve the overall image contrast (Fig. 26). In addition, the data acquisition requirements for CT systems provide for a high sensitivity and very wide dynamic range detector system.

Fig. 26 Digital radiograph of an aircraft engine turbine blade (nickel alloy precision casting) from an industrial CT system

Image Processing and Analysis. Because the DR and CT images are stored as a matrix of numbers, the computer can be used as a tool to obtain specific image information, to enhance images, or to assist in analyzing image data.

Display Features. A number of display features are used to obtain or present specific image information. A region-of-interest program defines a portion of the image and provides information on the pixel values within the region, such as minimum, maximum, and average CT number values; the standard deviation of the CT numbers; or the area or number of pixels contained in the region. A histogram plot can display the relative frequency of occurrence of CT number values.

Cursor functions can be used to point to specific features, to annotate the images, and to determine coordinate locations, distances between points, or angles between lines. A plot or profile can be generated from the CT numbers along a defined line.

Image Processing. The image itself can be processed to enhance boundaries and details or to smooth the image to reduce noise. Linear operators or filters used to sharpen the image, however, will increase the image noise, and smoothing filters that reduce noise also blur or decrease the sharpness of the image. These processing steps, however, can assist in improving the visibility of specific types of structures. Nonlinear processing techniques can be used to enhance or smooth the image while minimizing the detrimental effects of the processing. Nonlinear techniques include median filtering and smoothing limited to statistically similar pixel values; both techniques reduce the image noise while maintaining sharper boundary edges. These nonlinear techniques, however, typically require more computation and can be difficult to implement in fast array processors.

Image Analysis. Digital images can be analyzed for specific features or to measure definable parameters contained in the image data. Where the image-processing capabilities are generic for any image, automated image analysis software is written to analyze specific features in specific components. The software can verify the presence of specific necessary components or can search for defined indications. Automated analysis is generally computational intensive, and identifying a broad range of indications is a highly complex task. Consequently, the automated analysis of flaw indications has generally been limited to a few, narrowly scoped analysis tasks.

The automated measurement of specific design parameters of components can be more readily defined and implemented. The cross-sectional presentation of the component structure in the CT image allows for the measurement of critical dimensions, wall thicknesses, cord lengths, and curvatures. The automated measurement of critical wall thicknesses on complex precision castings is a standard feature on CT systems used in the manufacture of aircraft engine turbine blades (Fig. 10).

Planar and Three-Dimensional Image Reformation. Having a stack of adjacent cross-sectional CT slices characterizes the density distribution within the scanned volume in three dimensions. With this set of data in the computer, alternate planes through the object can be defined, and the CT image data corresponding to these planes can be assembled. These CT planar reformations allow the presentation of CT images in planes other than the planes in which the data were originally acquired, including planes that CT data acquisition would not be feasible because of component size and shape (Fig. 27). The CT image data can also be presented along other nonplanar surfaces. The CT data that correspond to a conical surface on a rocket exit cone or along other structures can be presented. The data can also be reformatted to alternate coordinates, such as presenting the data for a tubular section with the horizontal axis of the display corresponding to an angular position and with the radial distance along the vertical axis of the display.

Fig. 27 CT image (a) across a sample helicopter tail rotor blade showing outer fiberglass airfoil and center composite spar. (b) Planar reformation through the composite spar from a series of CT slices. The dark vertical lines are normal cloth layup boundaries, while the mottling at the top is due to interplanar waviness of the cloth layup.

Structures within a scanned object can also be specifically characterized. Three-dimensional surface imaging identifies the surface of a structure in a stack of CT images, defines surface tiles corresponding to this surface, and produces a computer-assisted design perspective display of the structure, as shown in Fig. 11 (Ref 45). Because the CT images also display interior surfaces, the computer can be used to slice open these surface models to display interior features. These

capabilities hold the potential for improving the component design cycle by documenting the configuration of physical prototypes and operational components.

Computed tomography can also be used to define actual components, including their internal density distribution, as a direct input for finite-element analysis (FEA). Automated meshing techniques are being analyzed that could significantly reduce the time required to generate FEA models. In addition, this direct FEA modeling of actual components could assist in the nondestructive analysis and characterization of components that are to be failure tested and may allow improved calibration of the engineering models from the test data.

Dual Energy Imaging. In the range of x-ray energies used in industrial computed tomography, attenuation of the x-ray photons predominantly occurs by either photoelectric absorption or Compton scattering. The probability of attenuation due to photoelectric absorption decreases more rapidly than the probability of attenuation due to Compton scattering. Consequently, photoelectric absorption predominates at low energies, and Compton scattering is the primary interaction for high-energy photons. In addition, the probability for attenuation by photoelectric absorption is highly dependent on the atomic number of the absorber, while Compton scattering is relatively independent of atomic number.

These differences between photoelectric and Compton attenuation cause difficulties in correcting x-ray transmission data for beam hardening in structures having multiple materials. This difference in the attenuation process can be used, however, to obtain additional information on the composition of the scanned object (Ref 46). If the object is scanned at two separate energies, the data can be processed to determine a pair of images corresponding to the photoelectric and Compton attenuation differences. The pair of images can be a photoelectric and Compton image or can correspond to physical density and effective atomic number. This pair of basic images can be combined to form a CT image without beam hardening variations.

The data for the basis images are a result of the differences in the high- and low-energy scans and are highly sensitive to random variations. As a consequence, these basis images tend to have a very high noise level. The image noise level for the combined pseudo-monoenergetic image, however, is equivalent to or lower than the noise in either of the original single energy images. Accurate implementation of dual energy processing requires consistent data between the high- and low-energy scans and characterization of the differences, such as that due to the detection of Compton scatter. Dual energy imaging can also be implemented with the DR data to determine the basis data corresponding to the sum along the measured ray paths.

Partial Angle Imaging. All of the CT imaging techniques discussed have considered the ability to obtain transmission data from all angles in the plane of the cross-sectional slice. This is highly suitable for objects that can be readily contained within a tight cylindrical workspace, but it can be impractical for large planar structures. Other components, such as large ring and tubular structures, can be conventionally scanned given a large enough workspace, but it is advantageous to minimize the source-to-detector distance and to image through a single wall in order to have reasonable x-ray intensities and inspection throughput.

Methods have been investigated for medical imaging for reconstruction from partial data sets. Industrial imaging has the advantage, however, in being able to apply *a priori* information from the component design or from measured external contours to compensate for the missing data (Ref 47).

Another related approach is to use methods based on the focal-plane tomography or laminography techniques developed in the early 1920s. Focal-plane tomography involves moving the x-ray source and film relative to the object such that features in the object are blurred, except for the features in the focal plane. This method does not necessarily eliminate all of the structures outside of the focal plane as in computed tomography, however, the data are obtained without circling the object.

The capabilities of the conventional focal-plane tomography approach can be enhanced by using digital processing techniques. With a series of digital radiographs, the images can be shifted and combined within the computer to yield a series of focal planes at different levels in the object from one set of data. In addition, image filtering can be applied, similar to the filtering in the filtered-backprojection CT reconstruction, to enhance the features in the focal plane and to improve the elimination of out of plane structures.

Industrial Computed Tomography

Michael J. Dennis, General Electric Company, NDE Systems and Services

Appendix 1: CT Reconstruction Techniques

Computed tomography requires the reconstruction of a two-dimensional image from the set of one-dimensional radiation measurements. It is useful to know some of the basic concepts of this process in order to understand the information presented in the CT image and the factors that can affect image quality.

The reconstruction process consists of two basic steps:

- The conversion of the measured radiation intensities into projection data that correspond to the sum or projection of x-ray densities along a ray path
- The processing of the projection data with a reconstruction algorithm to determine the point-by-point distribution of the x-ray densities in the two-dimensional image of the cross-sectional slice

The development of projection data is common to all CT reconstruction techniques, while the reconstruction algorithm can be approached by one of several mathematical methods (Ref 48, 49, 50).

Of the various reconstruction algorithms developed for computed tomography, there are two basic methods: transform methods and iterative methods. Transform methods are based on analytical inversion formulas of the projection data values given by Eq 9. Transform methods are fast compared to iterative methods and produce good-quality images. The two main types of transform methods are the filtered-backprojection algorithm and the direct Fourier algorithm. The filtered-backprojection technique is the most commonly used method in industrial CT systems.

Projection Data

The first step in the reconstruction of a CT image is the calculation of projection data. The measured transmitted intensity data are normalized by the expected unattenuated intensity (intensity without the object). A logarithm is taken of these relative intensity measurements to obtain the projection data. The projection data values correspond to the integral or sum of the linear attenuation coefficient values along the line of the transmitted radiation. The reconstruction process seeks to determine the distribution of linear attenuation coefficients (or x-ray densities) in the object that would produce the measured set of transmission values.

The projection data values for a narrow monoenergetic beam of x-ray radiation can be theoretically modelled by first considering Lambert's law of absorption:

$$I = I_0 \exp(-\mu s) \quad (\text{Eq 6})$$

where I is the intensity of the beam transmitted through the absorber, I_0 is the initial intensity of the beam, s is the thickness of the absorber, and μ is the linear attenuation coefficient of the absorber material. The linear attenuation coefficient corresponds to the fraction of a radiation beam per unit thickness that a thin absorber will attenuate (absorb

and scatter). This coefficient is dependent on the atomic number of the materials and on the energy of the x-ray beam and is proportional to the density of the absorber.

If instead of a single homogenous absorber there were a series of absorbers, each of thickness s , the overall transmitted intensity would be:

$$I = I_0 \exp[(\mu_1 + \mu_2 + \mu_3 \dots + \mu_i)s] \quad (\text{Eq 7})$$

where μ_i is the linear attenuation coefficient of the i th absorber.

Considering a two-dimensional section through an object of interest, the linear attenuation coefficients of the material distribution in this section can be represented by the function, $\mu(x, y)$, where x and y are the Cartesian coordinates specifying the location of points in the section. Using the integral equivalent to Eq 7, the intensity of radiation transmitted along a particular path is given by:

$$I = I_0 \exp \left[- \int_{\text{source}}^{\text{detector}} \mu(x, y) ds \right] \quad (\text{Eq 8})$$

where ds is the differential of the path length along the ray. The objective of the reconstruction program in a CT system is to determine the distribution of $\mu(x, y)$ from a series of intensity measurements through the section. Dividing both sides of Eq 8 by I_0 and taking the natural logarithm of both sides of the equation yields the projection value, p , along the ray:

$$P = \ln \left(\frac{I_0}{I} \right) = \int_{\text{source}}^{\text{detector}} \mu(x, y) ds \quad (\text{Eq 9})$$

Equation 9, known as the Radon transformation of $\mu(x, y)$, is a fundamental equation of the CT process. It states that taking the logarithm of the ratio of the unattenuated intensity to the transmitted intensity yields the line integral along the path of the radiation through the two-dimensional distribution of linear attenuation coefficients. The inversion of Eq 9 was solved in 1917, when Radon demonstrated in principle that $\mu(x, y)$ could be determined analytically from an infinite set of these line integrals. Similarly, given a sufficient number of projection values (or line integrals) in tomographic imaging, the cross-sectional distribution, $\mu(x, y)$, can be estimated from a finite set of projection values.

The projection value as determined by Eq 9 is based on several assumptions that are not necessarily true in making practical measurements. If an x-ray source is used, the x-ray photon energies or spectra range from very low energies up to energies corresponding to the operating voltage of the x-ray tube. The energy of a beam can be characterized by an effective or average energy. The effective energy, as well as the associated linear attenuation coefficients of the material, will vary with the amount of material of filtration through which the beam passes. The increase in effective energy caused by the preferential absorption of the less penetrating, lower-energy photons when passing through increasing thicknesses of material is referred to as beam hardening. Beam hardening can cause nonlinearities in the measured projection values relative to Eq 9 and can cause shading artifacts in the image. With knowledge of the type of material in the object being imaged, corrections can be made to minimize this effect.

Other variations may also, occur in measuring the transmitted intensity values and determining the projection values. These include the measurement of scatter radiation, the stability of the x-ray source, or any intensity or time-dependent nonlinearities of the detector. To the extent that these systemic variations can be characterized or monitored, they can be corrected in the data processing. Another variance that cannot be eliminated is the statistical noise of the measurement due to the detection of a finite number of photons.

Direct Fourier Reconstruction Technique

The direct Fourier reconstruction technique utilizes the Fourier transformation of projection data. A Fourier transform is a mathematical operation that converts the object distribution defined in spatial coordinates into an equivalent sinusoidal amplitude and phase distribution in spatial frequency coordinates. The one-dimensional Fourier transformation of a set of projection data at a particular angle, θ , is described mathematically by:

$$P(\rho, \theta) = \int_{-\infty}^{\infty} p(r, \theta) \exp[-2\pi\rho r] dr \quad (\text{Eq 10})$$

where r is the spatial position along the set of projection data and ρ is the corresponding spatial frequency variable.

Fourier reconstruction techniques (and the filtered-backprojection method) are based on a mathematical relationship known as the central projection theorem or central slice theorem. This theorem states that the Fourier transform of a one-dimensional projection through a two-dimensional distribution is mathematically equivalent to the values along a radial line through the two-dimensional Fourier transform of the original distribution. For example, given one set of projection data measurements (Eq 9) through an object at a particular angle, taking the one-dimensional Fourier transform (Eq 10) of this data profile provides data values along one spoke in frequency space (Fig. 28). Repeating this process for a number of angles defines the two-dimensional Fourier transform of the object distribution in polar coordinates (Fig. 28b). Taking the inverse two-dimensional Fourier transform of this polar data array yields the object distribution in spatial coordinates.

Fig. 28 Data points in (a) direct space and (b) frequency space. The data points obtained in the orientation shown in (a) correspond to the data points on one spoke in the two-dimensional Fourier transform space (b).

Although the direct Fourier technique is potentially the fastest method, the technique has not yet achieved the image quality of the filtered-backprojection method, because of interpolation problems. Typical computer methods and display systems are based on rectangular grids rather than polar distributions, and several variations of the direct Fourier reconstruction technique exist for interpolating the data from polar coordinates to a Cartesian grid (usually interpolating the data in the spatial frequency domain). The interpolation techniques can be complex, and the quality of the images from measured data have generally been poorer than some of the other reconstruction methods. Interesting results have been obtained in industrial multiplanar microtomography research, but this method is not typically used in commercial systems (Ref 51).

Filtered-Backprojection Technique

The filtered-backprojection technique is the most commonly used CT reconstruction algorithm. Before discussing this method, a brief discussion of filtering and the simple backprojection method is provided.

Convolutions and Filters. A convolution is a mathematical operation in which one function is smeared by another function. Mathematically it can be defined as:

$$g(x) = f(x) * h(x) \tag{Eq 11}$$

$$g(x) = \int_{-\infty}^{\infty} f(x) h(x-u) du \tag{Eq 12}$$

for one dimension, or

$$g(x,y) = f(x,y) * h(x,y) \tag{Eq 13}$$

$$g(x,y) = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} f(x,y) h(x-u,y-v) du dv \tag{Eq 14}$$

for two dimensions where * is the symbol for the convolution operation. If the system is a digital system with a discrete number of samples, the corresponding equation to Eq 12 is:

$$g_i = \sum_{k=-\infty}^{\infty} f_i h_{i+k} \tag{Eq 15}$$

and two-dimensional equivalent to Eq 13 is:

$$g_{i,j} = \sum_{k=-\infty}^{\infty} \sum_{l=-\infty}^{\infty} f_{i,j} h_{i+k,j+l} \tag{Eq 16}$$

Convolutions are a common physical operation in data acquisition and imaging systems whether or not the term convolution is used. All imaging systems have limitations in their ability to reproduce an object faithfully. One method of quantifying the quality of an image is to define its point spread function or blurring function. A measured image is the convolution of the object function with this blurring function (Fig. 29). This is represented in Eq 13, in which $g(x, y)$ is the resultant image formed by convoluting the object function $f(x, y)$ with the blurring function $h(x, y)$. If the object function was an infinitely small target or a point, then $f(x, y)$ is a delta function with a value of zero everywhere but at one location, and the image $g(x, y)$ will be equal to the PSF, $h(x, y)$. This is how the point spread function is defined and measured.

Fig. 29 Convolution operation (*) in which a distribution $f(x)$ is blurred by a function $h(x)$ to form the blurred distribution $g(x)$. The function $h(x)$ is analogous to the PSF of an image system or a smoothing convolution filter in image processing.

Convolutions can also be used in image processing to smooth (Fig. 29) or sharpen (Fig. 30) an image. Smoothing convolution filters are typically square (averaging) or bell shaped, while sharpening convolution filters often have a positive value in the center, with adjacent values being negative.

Fig. 30 Convolution operation with the sharpening filter $h'(x)$. This sharpening of $g(x)$ [or a restoration of $f(x)$ with the "inverse" of $h(x)$] is analogous to image process filtering or to the filtering of the projection data in the filtered-backprojection reconstruction technique.

Reference has already been made to Fourier transforms, as in Eq 10, and to their ability to transform spatial data into corresponding spatial frequency data. Filtering operations, such as image smoothing or sharpening, can be readily performed on the data in the spatial frequency domain. According to the convolution theorem, convolution operations in the spatial domain correspond to simple function multiplications in the spatial frequency domain (Fig. 31), that is:

$$g(x) = f(x) * h(x) \quad (\text{Eq 17})$$

is equivalent to

$$G(\xi) = F(\xi) H(\xi) \quad (\text{Eq 18})$$

where $G(\xi)$, $F(\xi)$, and $H(\xi)$ are the Fourier transformed functions of $g(x)$, $f(x)$, and $h(x)$, where ξ is the spatial frequency conjugate of x . The functional multiplication in Eq 18 is simply the multiplication of the values of $F(\xi)$ and $H(\xi)$ at every value of ξ . The two-dimensional convolution of Eq 13 has its counterpart to Eq 18 where the functions G , F , and H are the two-dimensional Fourier transforms of $g(x, y)$, $f(x, y)$, and $h(x, y)$. Note that the spatial frequency variable, ξ , has units of 1/distance.

Fig. 31 The process of filtering according to the convolution theorem. Filtering operations can be performed as a convolution (*) of the spatial functions, (top) or as a multiplication (x) of the Fourier transform of these functions (bottom). Either technique can be used in the filtered-backprojection reconstruction process.

Because the blurring or convolution process is represented in the spatial frequency domain as a simple functional multiplication, the blurred image conceptually can be easily restored to a closer representation of the original object distribution. If the Fourier transform of the image, $G(\xi)$, is filtered by multiplying by the function $H'(\xi)$ where $H'(\xi) = 1/H(\xi)$, the result is the original object frequency distribution, $F(\xi)$. In practice, this restoration is limited by the frequency limit of $H(\xi)$ leading to division by zero, and by the excessive enhancement of noise along with the signal at frequencies with small $H(\xi)$ values. This restoration process or "deconvolution" of the blurring function can likewise be performed as a convolution in the spatial domain as illustrated in Fig. 30.

Backprojection is the mathematical operation of mapping the one-dimensional projection data back into a two-dimensional grid. This is done intuitively by radiographers in interpreting x-ray films. If a high-density inclusion or structure is visible in two or more x-ray films taken at different angles, the radiographer can mentally backproject along the corresponding ray paths to determine the intersection of the rays and the location of the structure in space.

Mathematically, this is done by taking each point on the two-dimensional image grid and summing the corresponding projection value from each angle from which projection data were acquired. This backprojection process yields a maximum density at the location of the structure where the lines from the rays passing through this structure cross (Fig. 3a). The resultant image is not an accurate representation of the structure, however, in that these lines form a star artifact (Fig. 3a) extending in all directions from the location of the high-density structure. For a very large number of projection angles, the density of this structure is smeared over the entire image and decreases in amplitude with $1/r$, where r is the distance from the structure. This simple backprojected image, f_b , can be represented by the convolution of the true image, f , with the blurring function, $1/r$, or:

$$f_b(r, \theta) = f(r, \theta) * (1/r) \quad (\text{Eq 19})$$

With ideal data, this blurring function can be removed by a two-dimensional deconvolution or filtering of the blurred image. The appropriate filtering function can be determined by using the convolution theorem to transform Eq 19 into its frequency domain equivalent of:

$$F_b(\rho, \theta) = F(\rho, \theta) (1/\rho) \quad (\text{Eq 20})$$

where the function $(1/\rho)$ is the Fourier transform of $1/r$ in polar coordinates. Dividing both sides by $(1/\rho)$ yields:

$$F(\rho, \theta) = \rho F_b(\rho, \theta) \quad (\text{Eq 21})$$

Therefore, the corrected image, f , can be obtained by determining a simple backprojection, f_b , taking its Fourier transform, filtering, and then taking the inverse Fourier transform to get back into spatial coordinates. Alternatively, the filter function, ρ , can be transformed into spatial coordinates, and the backprojected image can be corrected by a two-dimensional convolution operation. Equations 19, 20, and 21 become somewhat more complex when evaluated in rectangular coordinates rather than as represented in polar coordinates.

This approach tends to produce poor results with actual data. Filtering out this blurring function from the projection data prior to backprojection, however, is quite effective and is the basis for the most commonly used reconstruction method, the filtered-backprojection reconstruction technique.

Filtered-Backprojection Reconstruction. According to the central slice theorem discussed in the section "Direct Fourier Reconstruction Technique" in this Appendix, the Fourier transform of the one-dimensional projection data through a two-dimensional distribution is equivalent to the radial values of the two-dimensional Fourier transform of the distribution. Consequently, the filtering operation performed in Eq 21 can be performed on the projection data prior to backprojection. This is the conceptual basis for the filtered-backprojection reconstruction technique (Ref 52, 53), and it is illustrated schematically in Fig. 3(b).

As with other filtering operations, this correction can be implemented as a convolution in the spatial domain or as a functional multiplication in frequency domain. Fourier filtered backprojection is performed by taking the measured projection data, Fourier transforming it into the frequency domain, multiplying by the ramp-shaped ρ filter (which enhances the high spatial frequencies relative to the low frequencies), taking the inverse Fourier transform of this corrected frequency data, and then backprojecting the filtered projection data onto the two-dimensional grid.

If the filtering is performed in the spatial domain by convoluting the measured projection data with a spatial filter equivalent to the inverse Fourier transform of ρ , the process is often referred to as the convolution-backprojection reconstruction method. The frequency filter has the shape of a ramp, enhancing the high frequency (or sharp detail information) of the projection data. Therefore, the convolution function, or kernel, has the expected shape for a sharpening filter. The positive central value is surrounded by negative values that diminish in magnitude with distance from the center. Because of the similar results obtained by Fourier filtering and convolution filtering and the uncertainty with which the filtering approach is often implemented on specific systems, the terms filtered-backprojection reconstruction and convolution-backprojection reconstruction are sometimes used interchangeably.

The filtered-backprojection reconstruction technique is the method that is commonly used in both medical and industrial tomography systems. The method is more tolerant of measured data imperfections than some of the other techniques. Filtered-backprojection reconstruction provides relatively fast reconstruction times and permits the processing of data after each view is acquired. With appropriate computational hardware, the displayed image can be available almost immediately after all the data have been acquired.

Variations in the filter functions used result from the physical limitations encountered with actual data (particularly its finite quantity) and the boundary assumptions made in the calculations. Additional windowing filters are sometimes combined with the theoretically derived filter to smooth or sharpen the image with no additional processing time.

Another variation used in special situations consists of combinations of the reconstruction techniques, such as performing a filtered-backprojection reconstruction followed by iterative processing. This may be beneficial in cases where the data set is limited and additional known information on the object's shape and content can be applied through the iterative steps to provide an improved image.

Iterative Reconstruction Techniques

Another broad category of methods is the iterative reconstruction algorithms. With this approach, an initial guess is made of the density distribution of the object. This initial guess may result from knowledge of the nominal design of the object or may assume a homogenous cylinder of some density. The computer then calculates the projection data values that would be measured for this assumed object. Each calculated value is compared to the corresponding measured projection data value, and the difference between these values is used to adjust the assumed density values along this ray path. This correction to the assumed distribution is applied successively for each measured ray. An iteration is completed when the image has been corrected along all measured rays, and the process begins again with the first ray. With each iteration, the approximated distribution (or reconstructed image) improves its correspondence to the object distribution.

There are numerous variations of iterative processing that may be additive or multiplicative, weighted or unweighted, restricted or unrestricted, and may specify the order in which the projection data are processed. Some of the more common techniques are the iterative least squares technique, the simultaneous iterative reconstruction technique, and the algebraic reconstruction technique (Ref 54, 55, 56).

Iterative reconstruction techniques are rarely used. They require all data to be collected before even the first iteration can be completed, and they are very process intensive. Iterative techniques may be beneficial for selected situations where the data set is limited or distorted. Iterative techniques can be effective with incomplete sets of projection data or with irregular data collection configurations. Known information about the object, such as the design, material densities, or external contours, can be used, along with optimization criteria, to aid in determining the solution. This can allow the reconstruction process to be less sensitive to missing or inaccurate projection data. In addition, reconstruction-dependent corrections can be incorporated into these techniques, such as spectral correction for multiple materials or attenuation corrections in emission computed tomography (SPECT) of radionuclide distributions.

Industrial Computed Tomography

Michael J. Dennis, General Electric Company, NDE Systems and Services

Appendix 2: Computed Tomography Glossary

- **Afterglow**
 - A detrimental property of a scintillator in which the emission of light continues for a period of time after the exciting radiation has been discontinued.
- **Algorithm**
 - A procedure for solving a mathematical problem by a series of operations. In computed tomography, the mathematical process used to convert the transmission measurements into a cross-sectional image. Also known as reconstruction algorithm.
- **Aliasing**
 - An artifact in discretely measured data caused by insufficient sampling of high-frequency data, with this high-frequency information falsely recorded at a lower frequency. See Nyquist sampling frequency.
- **Aperture, collimator**
 - The opening of the collimator enabling variations in the shape of the measured x-ray beam.
- **Archival storage**
 - Long-term storage of information. In computed tomography, this can be accomplished by storing the information on digital magnetic tape, on optical disk, or as images on x-ray film.
- **Array, data**
 - An ordered set or matrix of numbers.
- **Array, detector**
 - An ordered arrangement of individual detector elements that operates as a unit, such as a linear detector array.
- **Array processor**
 - A special-purpose computer processor used to perform special functions at high speeds.
- **Artifact**
 - An error or false structure in an image that has no counterpart in the original object.
- **Attenuation of x-rays**
 - Absorption and scattering of x-rays as they pass through an object.
- **Backprojection**
 - The process of mapping one-dimensional projection data back into a two-dimensional image array. A process used in certain CT reconstruction algorithms.
- **Beam hardening**
 - The increase in effective energy of a polyenergetic (for example, x-ray) beam with increasing attenuation of the beam. Beam hardening is due to the preferential attenuation of the lower-energy, or soft, radiation.
- **Capping**
 - Artifact characterized by dark shading or lowering of pixel values toward edges; opposite of cupping. Sometimes caused by an overcompensating beam hardening correction to the data.
- **CAT**
 - See computed tomography.
- **Collimator**
 - The x-ray system component that confines the x-ray beam to the required shape. An additional collimator can be located in front of the x-ray detector to further define the portion of the x-ray beam to be measured.
- **Computed tomography (CT)**
 - The collection of transmission data through an object and the subsequent reconstruction of an image corresponding to a cross section through this object. Also known as computerized axial tomography, computer-assisted tomography, or CAT scanning.
- **Contrast-detail-dose diagram**
 - A plot of the minimum percent contrast needed to resolve a feature versus the feature size. The ability to visualize low-contrast structures tends to be limited by image noise, while small high-contrast structures are resolution limited.
- **Contrast scale**
 - The change of CT number that occurs per given change in linear attenuation coefficient. Contrast scale is dependent on the x-ray beam energy and the scaling parameters in the reconstruction process.
- **Contrast sensitivity**
 - The ability to differentiate material density (or linear attenuation coefficient) differences with respect to the surrounding material.

- **Convolution**
 - A mathematical process used in certain reconstruction algorithms. An operation between two functions in which one function is blurred or smeared by another function.
- **Coronal plane**
 - A medical term for a plane that divides the body into a front and back section. A y-z planar presentation, which may be mathematically constructed from a series of cross-sectional slices. See sagittal plane and reformation, planar.
- **Crosstalk, detector**
 - The unwanted pickup of the signal associated with neighboring detector elements. Crosstalk may be caused by radiation scatter or electronic interference.
- **CT numbers**
 - The numbers used to designate the x-ray attenuation in each picture element of the CT image.
- **Cupping**
 - Artifact characterized by dark shading in the center of the field of view. May be caused by beam hardening.
- **Data acquisition system (DAS)**
 - The components of a CT system used to collect and digitize the detected x-ray signal.
- **Density resolution**
 - The measure of the smallest density difference of an image structure that can be distinguished.
- **Detectability, low contrast**
 - The minimum detectable object size for a specified percent contrast between the object and its surroundings as measured with a test phantom.
- **Detective quantum efficiency (DQE)**
 - The fraction of the beam intensity needed to produce the same signal-to-noise ratio as a particular detector if it were replaced with an ideal detector. Also known as the quantum detection efficiency.
- **Detector aperture**
 - The physical dimensions of the active area of the detector, including any restriction by the detector collimation. Used in particular for the detector dimension in the plane of the CT scan.
- **Detector, x-ray**
 - Sensor array used to measure the x-ray intensity. Typical detectors are high-pressure gas ionization, scintillator-photodiode detector arrays, and scintillator-photomultiplier tubes.
- **Digital radiography (DR)**
 - Radiographic imaging technology in which a two-dimensional set of x-ray transmission measurements is acquired and converted to an array of numbers for display with a computer. Computed tomography systems normally have DR imaging capabilities. Also known as digital radioscopy.
- **Display resolution**
 - Number of picture elements (pixels) per unit distance in the object.
- **Dual energy imaging**
 - The process of taking two identical scans (DR or CT) at two different x-ray energies and processing the data to produce alternate images that may be insensitive to beam hardening artifacts or may be particularly sensitive to physical density, or the effective atomic number of the materials contained in the object.
- **Dynamic range**
 - The range of operation of a device between its upper and lower limit. This range can be given as a ratio (example 100:1) of the upper to lower limits, the number of measurable steps between the upper and lower limits, the number of bits (needed to record this number of measurable steps), or the minimum and maximum measurable values.
- **Edge enhancement**
 - A mathematical manipulation in which rapid density changes are enhanced or sharpened by means of differentiation or high-pass filters. This operation will also increase image noise.
- **Effective atomic number**
 - For an element, the number of protons in the nucleus of an atom. For mixtures, an effective atomic number can be calculated to represent a single element that would have attenuation properties identical to those of the mixture.
- **Effective x-ray energy**
 - The monoenergetic beam energy that is attenuated to the same extent by a thin absorber as is the given polyenergetic x-ray beam.
- **Field-of-view (FOV)**

- The maximum diameter of an object that can be imaged. Also known as scan FOV. The object dimension corresponding to the full width of a displayed image (display FOV).
- **Focal spot**
 - The area of the x-ray tube from which the x-rays originate. The effective focal-spot size is the apparent size of this area when viewed from the detector.
- **Fourier transformation**
 - A mathematical process for changing the description of a function by giving its value in terms of its sinusoidal spatial (or temporal) frequency components instead of its spatial coordinates (or vice versa).
- **Full width at half maximum (FWHM)**
 - A parameter that can be used to describe a distribution such as the point spread function.
- **Geometries, CT**
 - The geometrical configuration and mechanical motion to acquire the x-ray transmission data. Typically, parallel beam data are acquired from translate-rotate data acquisition, and fan beam data are obtained from rotate-only movement of the object (or of the source and detector about the object).
- **Histogram**
 - A plot of frequency of occurrence versus the measured parameter. In a CT image, the plot of the number of pixels with a particular CT number value versus CT number.
- **Histogram equalization**
 - An image display process in which an equal number of image pixels is displayed with each displayable gray shade or color.
- **Hysteresis**
 - Dependence of a measured signal on the previous measurement history.
- **Intensity**
 - The energy per unit area per unit time incident on a surface.
- **Ionization**
 - The process in which neutral atoms become charged by gaining or losing an electron.
- **Iterative reconstruction**
 - A method of reconstruction that produces an improving series of estimated images that is repeated until a suitable quality level is obtained.
- **Kernel**
 - A function that is convoluted with a data function. The kernel in the convolution-backprojection reconstruction algorithm can be modified to enhance sharpness or reduce noise. Also known as convolution kernel.
- **Kiloelectron volt (keV)**
 - A unit of energy usually associated with individual particles. The energy gained by an electron when accelerated across 1000 V.
- **Linear attenuation coefficient**
 - The fraction of an x-ray beam per unit thickness that a thin object will absorb or scatter (attenuate). A property proportional to the physical density and dependent on the atomic number of the material and the energy of the x-ray beam.
- **Linearity, detector**
 - A measure of the consistency in detector sensitivity versus the radiation intensity level.
- **Matrix**
 - An array of numbers arranged in two dimensions (rows and columns).
- **Megaelectron volt (MeV)**
 - A unit of energy usually associated with a particle. The energy gained by an electron accelerated across 1,000,000 V.
- **Modulation transfer function (MTF)**
 - A measure of the spatial resolution of an imaging system that involves the plot of image contrast (system response) versus the spatial frequency (line pairs per millimeter) of the contrast variations on the object being imaged. A plot of these two variables gives a curve representing the frequency response of a system. The MTF can also be determined from the Fourier transform of the point spread function.
- **Noise**
 - Salt-and-pepper appearance of an image caused by variations in the measured data. Image noise can be affected by choice of reconstruction algorithm and by image processing, such as sharpening and smoothing operations.
- **Noise, quantum (or photon)**

- Noise due to statistical variations in the number of x-ray photons detected. An increase in the number of photons measured decreases the relative quantum noise.
- **Noise, structural**
 - Unwanted detail of an object from overlying structures or due to granularity or material structure.
- **Noise, structured**
 - Nonrandom noise, such as due to reconstruction algorithm filtering or systemic errors in the measurements.
- **Nyquist sampling frequency**
 - The ability to characterize a signal from a series of discrete samples requires that the signal be sampled at a minimum of twice the frequency of the highest frequency contained in the signal. The undersampling of a signal causes the high-frequency signals to mimic or appear as lower-frequency signals, an effect termed aliasing.
- **Partial volume artifact**
 - Streaking or shadowing artifacts caused by high-density structures partially intercepting the finite-sized measured x-ray beam. The effect is due to the summation of multiple ray paths in an inhomogenous mixture.
- **Partial volume effect**
 - The effect of measuring a density lower than the true structure density due to the fact that only a part of the structure is within the measured voxel, that is, within the full slice width or resolution element.
- **Phantom**
 - A test object used to measure the response of the CT system. Phantoms can be used to calibrate the system or to measure performance parameters.
- **Photodiode**
 - A semiconductor device that permits current flow proportional to the intensity of light striking the diode junction.
- **Photomultiplier tube (PMT)**
 - A light-sensitive vacuum tube with multiple electrodes providing a highly amplified electrical output.
- **Photon**
 - A quantum, or particle, of electromagnetic radiation (such as light or x-rays).
- **Pixel**
 - Shortened term for picture element. A pixel is the smallest displayable element of an image; a single value of the image matrix. A pixel corresponds to the measurement of a volume element (voxel) in the object.
- **Point spread function (PSF)**
 - The image response of a system to a very small, high-amplitude object; the image blurring function.
- **Polychromatic**
 - Photons with a mixture of colors, or energies. Same as polyenergetic.
- **Polychromatic artifacts**
 - Image distortion such as image shading or low-density bands between high-density structures caused by the polychromatic x-ray beam. When an x-ray beam travels a longer path or through a high-absorption region, the low-energy components of the polychromatic beam are preferentially absorbed, resulting in a higher effective beam energy and creating artifacts in the image.
- **Polychromatic x-ray spectra**
 - An x-ray beam that consists of a range of x-ray energies. The maximum amplitude and effective energy of an x-ray beam are always less than the corresponding voltage applied to the tube. The maximum energy of an x-ray beam corresponds to the peak x-ray tube voltage.
- **Projection**
 - A set of contiguous measured line integrals (projection data points) through an object. May be parallel ray or divergent (fan) ray projection data set. Also called a view.
- **Projection data**
 - The logarithm of the normalized transmitted intensity data. The line integral of the linear attenuation coefficient through an object.
- **Quantum detection efficiency**
 - See detective quantum efficiency.
- **Radionuclide**
 - A specific radioactive material.
- **Reconstruction**

- The process by which raw digitized detector measurements are transformed into a cross-sectional CT image.
- **Reformation, planar**
 - A displayed image comparable to a measured CT image, but along a planar section that cuts across a series of measured CT slices. The computer selects the data corresponding to the selected plane from a stack of CT slices through a volume of the object.
- **Reformation, 3-D surface**
 - A perspective display of a structure; an image that appears as a photograph of the structure.
- **Resolution, high contrast**
 - A measure of the ability of an imaging system to present multiple high-contrast structures and fine detail; measurements made with line pair gage or bar resolution phantom. See spatial resolution.
- **Resolution, low contrast**
 - The minimum detectable spacing between specified objects for a specified percent contrast between the objects and their background as measured with a test phantom.
- **Sagittal plane**
 - A medical term for a plane that divides the body into left and right sides. A y-z planar presentation, which can be mathematically constructed from a series of cross-sectional slices. See coronal plane and reformation, planar.
- **Scan**
 - The operation of acquiring the data for a CT or DR image. Sometimes used in reference to the CT or DR image.
- **Scattering of x-rays**
 - One of the two ways in which the x-ray beam interacts with matter and the transmitted intensity is diminished in passing through object. The x-rays are scattered in a direction different from the original beam direction. Such scattered x-rays falling on the detector do not add to the radiological image. Because they reduce the contrast in that image, steps are usually taken to eliminate the scattered radiation. Also known as Compton scatter.
- **Scintillator**
 - A material that produces a rapid flash of visible light when an x-ray photon is absorbed. The scintillator is coupled with a light-sensitive detector to measure the x-ray beam intensity.
- **Sharpening**
 - Image-processing technique that enhances edge contrast and increases image noise. The opposite of smoothing.
- **Slice**
 - The cross-sectional plane through an object that is scanned to produce the CT image. See also tomographic plane.
- **Slice thickness**
 - The height or z-axis dimension of the measured x-ray beam normally measured at the center of the object. The slice thickness along with the image resolution defines the size of the measured volume corresponding to a pixel CT value.
- **Slit-scan radiography**
 - Method of producing an x-ray image in which a thin x-ray beam produces the image one line at a time. A method used to reduce measured scatter radiation. The DR mode of most CT systems uses a slit-scan technique with a linear detector array.
- **Smoothing**
 - Image-processing technique that averages the image data, reducing edge sharpness and decreasing image noise. Opposite of sharpening.
- **Spatial resolution**
 - A measure of the ability of an imaging system to represent fine detail; the measure of the smallest separation between individually distinguishable structures. See resolution, high contrast, point spread function, and modulation transfer function.
- **Spectrum, x-ray**
 - The plot of the intensity or number of x-ray photons versus energy (or wavelength).
- **Test phantom**
 - See phantom.
- **Tomographic plane**

- A section of the part imaged by the tomographic process. Although in CT the tomographic plane or slice is displayed as a two-dimensional image, the measurements are of the materials within a defined slice thickness associated with the plane.
- **Tomography**
 - From the Greek "to write a slice or section." The process of imaging a particular plane or slice through an object.
- **View**
 - A set of measured parallel or fan beam data for a particular angle through the center of the object. Also known as a profile or projection.
- **Voxel**
 - Shortened term for volume element. The volume within the object that corresponds to a single pixel element in the image. The box-shaped volume defined by the area of the pixel and the height of the slice thickness.
- **Window, display**
 - The range of CT values in the image that are displayed. The display window can normally be adjusted interactively by the operator to view different density ranges in the reconstructed image data.

Neutron Radiography

Harold Berger, Industrial Quality, Inc.

Introduction

NEUTRON RADIOGRAPHY is a form of nondestructive inspection that uses a specific type of particulate radiation, called neutrons, to form a radiographic image of a testpiece. The geometric principles of shadow formation, the variation

of attenuation with testpiece thickness, and many other factors that govern the exposure and processing of a neutron radiograph are similar to those for radiography using x-rays or γ -rays. These topics are extensively covered in the article "Radiographic Inspection" in this Volume and will not be discussed here.

This article will deal mainly with the characteristics that differentiate neutron radiography from x-ray or γ -ray radiography, as discussed in Ref 1, 2, 3, 4, 5, 6, 7, 8, 9. Neutron radiography will be described in terms of its advantages for improved contrast on low atomic number materials, the discrimination between isotopes, or the inspection of radioactive specimens.

Neutron Radiography

Harold Berger, Industrial Quality, Inc.

Principles of Neutron Radiography

Neutron radiography is similar to conventional radiography in that both techniques employ radiation beam intensity modulation by an object to image macroscopic object details. X-rays or γ -rays are replaced by neutrons as the penetrating radiation in a through-transmission inspection. The absorption characteristics of matter for x-rays and neutrons differ drastically; the two techniques in general serve to complement one another.

Neutrons are subatomic particles that are characterized by relatively large mass and a neutral electric charge. The attenuation of neutrons differs from the attenuation of x-rays in that the processes of attenuation are nuclear rather than ones that depend on interaction with the electron shells surrounding the nucleus.

Neutrons are produced by nuclear reactors, accelerators, and certain radioactive isotopes, all of which emit neutrons of relatively high energy (fast neutrons). Because most neutron radiography is performed with neutrons of lower energy (thermal neutrons), the sources are usually surrounded by a moderator, which is a material that reduces the kinetic energy of the neutrons.

Neutron Versus Conventional Radiography. Neutron radiography is not accomplished by direct imaging on film, because neutrons do not expose x-ray emulsions efficiently. In one form of neutron radiography, the beam of neutrons impinges on a conversion screen or detector made of a material such as dysprosium or indium, which absorbs the neutrons and becomes radioactive, decaying with a short half-life. In this method, the conversion screen alone is exposed in the neutron beam, then immediately placed in contact with film to expose it by autoradiography. In another common

form of imaging, a conversion screen that immediately emits secondary radiation is used with film directly in the neutron beam.

Neutron radiography differs from conventional radiography in that the attenuation of neutrons as they pass through the testpiece is more related to the specific isotope present than to density or atomic number. X-rays are attenuated more by elements of high atomic number than by elements of low atomic number, and this effect varies relatively smoothly with atomic number. Thus, x-rays are generally attenuated more by materials of high density than by materials of low density. For thermal neutrons, attenuation generally tends to decrease with increasing atomic number, although the trend is not a smooth relationship. In addition, certain light elements (hydrogen, lithium, and boron), certain medium-to-heavy elements (especially cadmium, samarium, europium, gadolinium, and dysprosium), and certain specific isotopes have an exceptionally high capability of attenuating thermal neutrons (Fig. 1). This means that neutron radiography can detect these highly attenuating elements or isotopes when they are present in a structure of lower attenuation.

Fig. 1 Mass attenuation coefficients for the elements as a function of atomic number for thermal (4.0×10^{-21} J, or 0.025 eV) neutrons and x-rays (energy ~ 125 kV). The mass attenuation coefficient is the ratio of the linear attenuation coefficient, μ , to the density, ρ , of the absorbing material. Source: Ref 6

Thermal (slow) neutrons permit the radiographic visualization of low atomic number elements even when they are present in assemblies with high atomic number elements such as iron, lead, or uranium. Although the presence of the heavy metals would make detection of the light elements virtually impossible with x-rays, the attenuation characteristics of the elements for slow neutrons are different, which makes detection of light elements feasible. Practical applications of neutron radiography include the inspection of metal-jacketed explosives, rubber O-ring assemblies, investment cast turbine blades to detect residual ceramic core, and the detection of corrosion in metallic assemblies.

Using neutrons, it is possible to detect radiographically certain isotopes—for example, certain isotopes of hydrogen, cadmium, or uranium. Some neutron image detection methods are insensitive to background γ -rays or x-rays and can be used to inspect radioactive materials such as reactor fuel elements. In the nuclear field, these capabilities have been used to image highly radioactive materials and to show radiographic differences between different isotopes in reactor fuel and

control materials. The characteristics of neutron radiography complement those of conventional radiography; one radiation provides a capability lacking or difficult for the other.

Neutron Radiography

Harold Berger, Industrial Quality, Inc.

Neutron Sources

The excellent discrimination capabilities of neutrons generally refer to neutrons of low energy, that is, thermal neutrons. The characteristics of neutron radiography corresponding to various ranges of neutron energy are summarized in Table 1. Although any of these energy ranges can be used for radiography, this article emphasizes the thermal-neutron range, which is the most widely used for inspection.

Table 1 Characteristics of neutron radiography at various neutron-energy ranges

Type of neutrons	Energy range, J (eV)	Characteristics
Cold	$<1.6 \times 10^{-21}$ (<0.01)	High-absorption cross sections decrease transparency of most materials, but also increase efficiency of detection. An advantage is reduced scatter at energies below the Bragg cutoff, where neutrons can no longer undergo Bragg reflection.
Thermal	1.6×10^{-21} to 8.0×10^{-20} (0.01 to 0.5)	Good discrimination between materials, and ready availability of sources
Epithermal	8.0×10^{-20} to 1.6×10^{-15} (0.5 to 10^4)	Excellent discrimination for particular materials by working at energy of resonance. Greater transmission and less scatter in samples containing materials such as hydrogen and enriched reactor fuels
Fast	1.6×10^{-15} to 3.2×10^{-12} (10^4 to 2.0×10^7)	Good point sources are available. At low-energy end of spectrum, fast-neutron radiography may be able to perform many inspections done with thermal neutrons, but with a panoramic technique. Good penetration capability because of low-absorption cross sections in all materials. Poor material discrimination

In thermal-neutron radiography, an object (testpiece) is placed in a thermal-neutron beam in front of an image detector. The neutron beam may be obtained from a nuclear reactor, a radioactive source, or an accelerator. Several characteristics of these sources are summarized in Table 2. For thermal-neutron radiography, fast neutrons emitted by these sources must first be moderated and then collimated (Fig. 2). The radiographic intensities listed in Table 2 typically do not exceed 10^{-5} times the total fast-neutron yield of the source. Part of this loss is incurred in moderating the neutrons, and the remainder in bringing a collimated beam out of a large-volume moderator.

Table 2 Properties and characteristics of thermal-neutron sources

Type of source	Typical radiographic intensity, n/cm ² ·s	Spatial resolution	Exposure time	Characteristics
Radioisotope	10 ¹ to 10 ⁴	Poor to medium	Long	Stable operation, low-to-medium investment cost, possibly movable
Accelerator	10 ³ to 10 ⁶	Medium	Average	On-off operation, medium cost, possibly movable
Subcritical assembly	10 ⁴ to 10 ⁶	Good	Average	Stable operation, medium-to-high investment cost, movement difficult
Nuclear reactor	10 ⁵ to 10 ⁸	Excellent	Short	Medium-to-high investment cost, movement difficult

Fig. 2 Thermalization and collimation of beam in neutron radiography. Neutron collimators can be of the parallel-wall (a) or divergent (b) type. The transformation of fast neutrons to slow neutrons is achieved by moderator materials such as paraffin, water, graphite, heavy water, or beryllium. Boron is a typically used neutron-absorbing layer. The L/D ratio, where L is the total length from the inlet aperture to the detector (conversion screen) and D is the effective dimension of the inlet of the collimator, is a significant geometric factor that determines the angular divergence of the beam and the neutron intensity at the inspection plane.

Collimation is necessary for thermal-neutron radiography because there are no useful point sources of low-energy neutrons. Good collimation in thermal-neutron radiography is comparable to small focal-spot size in conventional radiography; the images of thick objects will be sharper with good collimation. On the other hand, it should be noted that available neutron intensity decreases with increasing collimation.

Nuclear Reactors. Many types of reactors have been used for thermal-neutron radiography. The high neutron flux generally available provides high-quality radiographs and short exposure times. Although truck-mounted reactors are technically feasible, a reactor normally must be considered a fixed-site installation, and testpieces must be taken to the reactor for inspection. Investment costs are generally high, but small medium-cost reactors can provide good results. When costs are compared on the basis of available neutron flux (typically, 10^{12} n/cm² · s flux is often available at collimator entrance, and 10^6 to 10^7 n/cm² · s flux is available at the film plane), reactor sources can be less costly than other sources.

Accelerators. The accelerators most often used for thermal-neutron radiography are:

- The low-voltage type employing the reaction ${}^3_1\text{H} + {}^2_1\text{H} \rightarrow {}^4_2\text{He} + {}^1_0\text{n}$, a (d,T) generator, where n, d, and T represent the neutron, deuteron (the nucleus of a deuterium atom, D or ${}^2_1\text{H}$, that consists of one neutron and one proton), and tritium (${}^3_1\text{H}$), respectively
- High-energy x-ray machines, in which (x,n) reactions are used, where x represents x-ray radiation
- Van de Graaff accelerators
- More recently, high-energy linear accelerators and cyclotrons to generate neutrons by charged-particle reactions on beryllium or lithium targets

Low-Voltage Accelerators. A (d,T) generator provides fast-neutron yields in the range of 10^{10} to 10^{12} n/s. Target lives in sealed neutron tubes are reasonable (100 to 1000 h, depending on yield), and the sealed-tube system presents a source similar to that of certain types of x-ray machines.

High-Energy X-Ray Machines. An (x,n) neutron source is a high-energy x-ray source such as a linear accelerator that can be converted for the production of neutrons by adding a suitable secondary target—for example, beryllium. X-rays having energies above an energy threshold level cause the secondary target to emit neutrons; in beryllium, the threshold x-ray energy for neutron production is 2.67×10^{-13} J (1.66 MeV). Useful neutron radiography has been performed with an 8.8×10^{-13} J (5.5 MeV) linear accelerator having an x-ray output of 0.17 C/kg · min (650 R/min) at 1 m (3 ft). Changeover time from neutron emission to x-ray emission for this source was only 1 h. Beam intensities for neutron radiography with this source were about 5×10^4 n/cm² · s. with reasonable beam collimation.

Van de Graaff Accelerators. Much higher beam intensities have been obtained by the acceleration of deuterons onto a beryllium target in a 3.2×10^{-13} J (2.0 MeV) Van de Graaff generator. An intensity of 1.2×10^6 n/cm² · s was achieved (with medium collimation), and it is estimated that an acceleration voltage of 4.8×10^{-13} J (3.0 MeV) would improve beam intensity by a factor of approximately six.

The principle of the Van de Graaff machine is illustrated in Fig. 3. A rotating belt transports the charge from a supply to a high-voltage terminal. An ion source within the terminal is fed deuterium gas from a reservoir frequently located within the terminal. A radio-frequency system ionizes the gas, and positive ions are extracted into the accelerator tube. The terminal voltage of about 3 MV is distributed by a resistor chain over about 80 gaps forming the accelerator tube, all of which is enclosed in a pressure vessel filled with insulating gas (N₂ and CO₂ at 2.0 MPa, or 290 psi).

Fig. 3 Cross section showing Van de Graaff principle as it is applied to neutron radiography. Source: Ref 6

The particle beam is extracted along flight tubes. In a typical neutron reaction, the beam bombards a water-cooled beryllium target in the center of the water moderator tank, which also serves as a partial shield. The higher-energy accelerators indicated above can provide neutron yields of 10^{13} n/s and moderated, well-collimated beam intensities of the order of 10^6 n/cm² · s.

A few 4.8×10^{-13} J (3.0 MeV) Van de Graaff generators have recently been placed in service for thermal-neutron radiography. In one such Van de Graaff system designed for neutron radiography, deuterons (4.8×10^{-13} J, or 3 MeV; 280 μ A) are accelerated onto a disk-shaped, water-cooled beryllium metal target. Neutrons in the range of 3.2 to 9.6×10^{-13} J (2 to 6 MeV) are emitted preferentially in the forward direction and are moderated in water. The 4π (solid angle) yield of 5×10^{11} n/s produces a peak thermal neutron flux of 2×10^9 n/cm² · s. At a collimator ratio of 36:1, the typical exposure time for high-quality film (3×10^9 n/cm²) is about 2 h.

The accelerator tank for the 4.8×10^{-13} J (3 MeV) machine measures 5.2 m (17 ft) in length and 1.5 m (5 ft) in diameter. The weight is 6100 kg (13,500 lb). The dimensions of the water tank are approximately 1 m (3 ft) on each side. Neutron beams can be extracted through three horizontal beam collimators. Unlike reactors, subcritical multipliers, or (d, T) accelerators, the Van de Graaff accelerators utilize no radioactive source material and sometimes require less stringent license processes.

Other acceleration machines or reactions can be used for thermal-neutron radiography. However, those described above have been most widely used.

Radioactive Sources. There are many possible radioactive sources. The characteristics of several radioisotopes that are commonly used are summarized in Table 3.

Table 3 Properties and characteristics of several radioisotopes used for thermal-neutron radiography

Radioisotope	Neutron reaction	Half-life	Characteristics
¹²⁴ Sb-Be	(γ , n)	60 days	Short half-life, high γ -ray background, low neutron energy easily thermalized, low cost, high neutron yield
²¹⁰ Po-Be	(α , n)	138 days	Short half-life, low γ -ray background, low cost
²¹⁴ Am-Be	(α , n)	458 years	Long half-life, easily shielded γ -ray background, high cost

^{241}Am - ^{242}Cm -Be	(α , n)	163 days	Short half-life, high neutron yield, medium cost
^{244}Cm -Be	(α , n)	18.1 years	Long half-life, low γ -ray background, potential low cost
^{252}Cf	Spontaneous fission	2.65 years	Long half-life, small size, low neutron energy easily thermalized, high neutron yield

Radioisotopes offer the best prospect for a portable neutron-radiographic facility, but it should be recognized that the thermal-neutron intensity is only about 10^{-5} of the total fast-neutron yield from the source. Consequently, neutron radiography using a radioisotope as a neutron source normally requires long exposure times and fast films. For example, a typical 3.7×10^{11} Bq (10 Ci) source would provide a total fast-neutron yield of the order of 10^7 n/s. The radiographic intensity would be about 10^2 n/cm² · s, and a typical exposure time using a fast film/converter-screen combination would be about 1 h. Californium-252, usually purchased in the form shown in Fig. 4, has been the most frequently used radioactive source for neutron radiography.

Fig. 4 Cross section of doubly encapsulated ^{252}Cf source. Source: Ref 6

Subcritical Assembly. Another type of source that has received some attention is a subcritical assembly. This type of source is similar to a reactor, except that the neutron flux is less and the design is such that criticality cannot be achieved. A subcritical assembly offers some of the same neutron multiplication features as a reactor. It is somewhat easier to operate, and safety precautions are less stringent, because it is not capable of producing a self-sustaining neutron chain reaction.

Neutron Radiography

Harold Berger, Industrial Quality, Inc.

Attenuation of Neutron Beams

Unlike electrons and electromagnetic radiation, which interact with orbital electrons surrounding an atomic nucleus, neutrons interact only with atomic nuclei. Usually, neutrons are deflected by interaction with the nuclei, but occasionally a neutron is absorbed into a nucleus. When a neutron collides with the nucleus of an atom and is merely deflected, the neutron imparts some of its kinetic energy to the atom. Both the neutron and the atom move off in different directions from the original direction of motion of the neutron. This process, known as scattering, reduces the kinetic energy of the neutron and the probability that the neutron will pass through the object (testpiece) in a direction that will permit it to be detected by a device placed behind the object.

True absorption of neutrons occurs when they are captured by nuclei. The capture of a neutron transforms the nucleus to the next-higher isotope of the target nucleus and sometimes produces an unstable nucleus that then undergoes radioactive decay. The probability that a collision between a neutron and a nucleus will result in capture is known as the capture cross section and is expressed as an effective area per atom. (The capture cross section is usually measured in barns, 1 barn equaling 10^{-24} cm² or 1.6×10^{-25} in.².) The capture cross section varies with neutron energy, atomic number, and mass number. For thermal neutrons (energy of about 4.0×10^{-21} J, or 0.025 eV), the average capture cross section varies randomly with atomic number, being high for certain elements and relatively low for other elements. The cross section actually varies by isotope rather than element. However, radiographers usually consider an average cross section for an element. For intermediate neutrons (energies of 8.0×10^{-20} to 1.6×10^{-15} J, or 0.5 eV to 10 keV) and for fast neutrons (energies exceeding 1.6×10^{-15} J, or 10 keV), the capture cross section is normally smaller than that for thermal neutrons, and there is much less variation with atomic number. For fast neutrons, most elements are similarly absorbing, and scattering is the dominant process of attenuation.

In relation to other types of penetrating radiation, many materials interact less with neutrons. Therefore, neutrons can sometimes be used to inspect greater thicknesses than can be conveniently inspected with electromagnetic radiation. The combined effect of scattering and capture can be expressed as a mass-absorption coefficient; this coefficient is used to determine the exposure factor for the neutron radiography of a given object (testpiece). For a given material, attenuation varies exponentially with thickness, and the basic law of radiation absorption (discussed in the article "Radiographic Inspection" in this Volume) applies to neutron attenuation as well as to the attenuation of electromagnetic radiation.

Neutron Radiography

Harold Berger, Industrial Quality, Inc.

Neutron Detection Methods

Detection methods for neutron radiography generally use photographic or x-ray films. In the so-called direct-exposure method, film is exposed directly to the neutron beam, with a conversion screen or intensifying screen providing the secondary radiation that actually exposes the film (Fig. 5a). Alternatively, film can be used to record an autoradiographic image from a radioactive image-carrying screen in a technique called the transfer method (Fig. 5b).

Fig. 5 Schematics of neutron radiography with film using the direct-exposure method (a) and the transfer method (b). The cassette is a light-tight device for holding film or conversion screens and film in close contact during exposure.

Direct-Exposure Method. Conversion screens of thin gadolinium foil or a scintillator have been most widely used in the direct-exposure method. When bombarded with a beam of neutrons, some of the gadolinium atoms absorb some of the neutrons and then promptly emit γ -rays. The γ -rays in turn produce internal conversion electrons that actually expose the film; these are directly related in intensity to the intensity of the neutron beam. Scintillators, on the other hand, are fluorescent materials often made of zinc sulfide crystals that also contain a specific isotope, such as ${}^6_3\text{Li}$ or ${}^{10}_5\text{B}$. In a neutron beam, these isotopes react with neutrons as follows:

The α particles emitted as a result of these reactions cause the zinc sulfide to fluoresce, which in turn exposes the film. Gadolinium oxysulfide, a scintillator originally developed for conventional radiography, is now widely used for neutron radiography.

Scintillators provide useful images with total exposures as low as $5 \times 10^5 \text{ n/cm}^2$. The high speed and favorable relative neutron/gamma response of scintillators make them attractive for use with nonreactor neutron sources. For high-intensity sources, gadolinium screens are widely used. Gadolinium screens provide greater uniformity and image sharpness (high-contrast resolution of $10 \mu\text{m}$, or $400 \mu\text{in.}$, has been reported), but an exposure about 30 or more times that of a scintillator is required, even with fast films. Excessive background radiation should be kept to a minimum because it can have a detrimental effect on image quality.

In the transfer method, a thin sheet of metal called a transfer screen, which is usually made of indium or dysprosium, is exposed to the neutron beam transmitted through the specimen. Neutron capture by the isotope ${}^{115}_{49}\text{In}$ or ${}^{164}_{66}\text{Dy}$ induces radioactivity, indium having a half-life of 54 min and dysprosium a half-life of 2.35 h. The intensity of radioactive emission from each area of the transfer screen is directly related to the intensity of the portion of the transmitted neutron beam that induced radioactivity in that area. The radiograph to be interpreted is made by placing the radioactive transfer screen in contact with a sheet of film. The β particle and γ -ray emissions from the transfer screen expose the film, with film density in various portions of the developed image being proportionally related to the intensity of radioactive emission.

The transfer method is especially valuable for inspecting a radioactive specimen. Although the radiation emitted by the specimen (especially γ -rays) causes heavy film fogging during conventional radiography or direct-exposure neutron radiography, the same radiation will not induce radioactivity in a transfer screen. Therefore, a clear image of the specimen can be obtained even when there is a high level of background radiation.

In comparing the two primary detection methods, the direct-exposure method offers high speed, unlimited image-integration time, and the best spatial resolution. The transfer method offers insensitivity to the γ -rays emitted by the specimen and greater contrast because of lower amounts of scattered and secondary radiation.

Real-time imaging, in which light from a scintillator is observed by a television camera, can also be used for neutron radiography. Because of low brightness, most real-time neutron radiographic images are enhanced by an image-intensifier tube, which may be separate or integral with the scintillator screen. This method can be used for such applications as the study of fluid flow in a closed system or the study of metal flow in a mold during casting. The lubricants moving in an operating engine have been observed with the real-time neutron imaging method.

Neutron Radiography

Harold Berger, Industrial Quality, Inc.

Applications

Various applications concerning the inspection of ordnance, explosive, aerospace, and nuclear components are discussed in Ref 1, 2, 3, 4, 5, 6, 7, 8, 9. The presence, absence, or correct placement of explosives, adhesives, O-rings, plastic components, and similar materials can be verified. Nuclear fuel and control materials can be inspected to determine the distribution of isotopes and to detect foreign or imperfect material. Ceramic residual core in investment cast turbine blades can be detected. Observations of corrosion in metal assemblies are possible because of the excellent neutron sensitivity to the hydrogenous corrosion product. Hydride deposition in metals and diffusion of boron in heat treated boron-fiber composites can be observed. The following examples illustrate the application of neutron radiography to the inspection of radioactive materials and several assemblies of metallic and nonmetallic components.

Example 1: Thermal-Neutron Radiography Used to Determine Size of Highly Radioactive Nuclear Fuel Elements.

Highly radioactive nuclear fuel elements required size measurements to determine the extent of dimensional changes that may have occurred during irradiation. Generally, inspection is done in a hot cell, but because hot-cell inspection is a relatively long, tedious, and costly procedure, neutron radiography was selected.

The fuel elements to be inspected consisted of 6.4 mm ($\frac{1}{4}$ in.) diam cylindrical pellets of $\text{UO}_2\text{-PuO}_2$; the plutonium content was 20%, and the uranium was enriched in ^{235}U . The pellets had been irradiated to 10% burnup, which resulted in a level of radioactivity of 3×10^{-2} C/kg · h (10 KR/h) at 0.3 m (1 ft).

Five elements were selected for inspection. A neutron radiograph was taken by activating 0.25 mm (0.010 in.) thick dysprosium foil with a transmitted beam of thermal neutrons. An autoradiograph of the activated-dysprosium transfer screen on a medium-speed x-ray film yielded the result shown in the positive print in Fig. 6.

Fig. 6 Positive print of a thermal-neutron radiograph of five irradiated nuclear fuel elements, taken to determine if dimensional changes occurred during irradiation. Radiograph was made using a dysprosium transfer-screen method. Dark squares in middle element are voids.

Both ^{235}U and plutonium have high attenuation coefficients for thermal neutrons. The high contrast of the fuel pellets made it possible to measure pellet diameter directly from the neutron radiographs. These measurements were both repeatable and statistically significant within 0.013 mm (0.0005 in.). Later, radiographic measurements were compared with physical measurements made in a hot cell. The two sets of values corresponded within 0.038 mm (0.0015 in.).

Example 2: Indium-Resonance Technique for Determining Internal Details of Highly Radioactive Nuclear Fuel Elements.

The five nuclear fuel elements inspected for dimensional changes in Example 1 were further inspected for internal details. This was necessary because the thermal-neutron inspection procedure did not reveal any internal details; it only shadowed the pellets, as shown by the positive print in Fig. 6.

To inspect for internal details, an indium-resonance technique, which utilizes epithermal neutrons, was used. In this technique, a collimated neutron beam was filtered by 0.5 mm (0.02 in.) of cadmium to remove most of the thermal neutrons. Filtering produced a neutron beam with a nominal average energy somewhat above thermal. The epithermal-neutron beam passed through the fuel elements and activated a sheet of indium foil. Neutrons with an energy of about 2.34×10^{-19} J (1.46 eV), which is the resonance-absorption energy for indium, were primarily involved in activation. The positive print of a radiograph made with epithermal neutrons shown in Fig. 7 reveals considerable internal details, in contrast to the lack of internal details in Fig. 6.

Fig. 7 Positive print of a neutron radiograph of the same five nuclear fuel elements shown in Fig. 6. Radiograph was made with epithermal neutrons and an indium-resonance technique, and it reveals internal details not shown in the thermal-neutron radiograph in Fig. 6

With epithermal neutrons, there was less attenuation by the fuel elements than with thermal neutrons. Therefore, internal details that were not revealed by thermal-neutron radiography--such as cracking or chipping of fuel pellets, and dimensional features of the central void in the fuel pellets (including changes in size and accumulation of fission products)--were revealed with the indium-resonance technique.

Example 3: Use of Conventional and Neutron Radiography to Inspect an Explosive Device for Correct Assembly.

Small explosive devices assembled from both metallic and nonmetallic components required inspection to ensure correct assembly. The explosive and the components made of paper, plastic, or other low atomic number materials, which are less transparent to thermal neutrons than to x-rays, could be readily observed with thermal-neutron radiography. Metallic components were inspected by conventional x-ray radiography.

A positive print of a thermal-neutron, direct-exposure radiograph of a 50 mm (2 in.) long explosive device is shown in Fig. 8(a). The radiograph was made on Industrex R film (Eastman Kodak), using a gadolinium-foil screen. Total exposure was 3×10^9 n/cm², which was achieved with an exposure time of 4 to 5 min. At the top in Fig. 8(a), just inside the stainless steel cap, can be seen a line image that corresponds to a moisture absorbent made of chemically treated paper. Below the paper is a mottled image, which is the explosive charge. Below the explosive charge are plastic components and, at the very bottom, epoxy.

Fig. 8 Comparison of positive prints of a thermal-neutron radiograph (a) and a conventional radiograph (b) of a 50 mm (2 in.) long explosive device. Neutron radiograph reveals details of paper, explosive compound, and plastic components not revealed by x-rays.

A conventional radiograph of the same device is shown in Fig. 8(b). The metallic components, which were poorly delineated in the thermal-neutron radiograph, are more clearly seen in Fig. 8(b). Together, the two radiographs verified that both metallic and nonmetallic components were correctly assembled.

Example 4: Use of Neutron Radiography to Detect Corrosion in Aircraft Components.

Aluminum honeycomb components are extensively used for aircraft construction. The aluminum material is subject to corrosion if exposed to water or humid environments. Thermal-neutron radiography is an excellent method of detecting hidden corrosion in these assemblies. The corrosion products are typically hydroxides or water-containing oxides; these

corrosion products contain hydrogen, a material that strongly attenuates thermal neutrons. The aluminum metal, on the other hand, is essentially transparent to the neutrons. Therefore, a thermal-neutron radiograph of a corroded aluminum honeycomb assembly shows the corrosion product and other attenuating components such as adhesives and sealants. Figure 9 depicts a thermal-neutron radiograph of an aluminum honeycomb assembly showing the beginnings of corrosion. The white line image across the middle of the radiograph represents the adhesive coupling together two core sections. The faint white smears in the upper half of the image and the double dot in the lower left area are images of corrosion as disclosed by the thermal-neutron radiograph. Developmental work has shown that thermal-neutron imaging techniques are capable of detecting the corrosion product buildup represented by an aluminum metal loss of 25 μm (1000 $\mu\text{in.}$). The neutron method, therefore, is a very sensitive technique for the detection of corrosion.

Fig. 9 Thermal-neutron radiograph of aluminum honeycomb aircraft component showing early evidence of hydrogen corrosion. See text for discussion. Courtesy of D. Froom, U.S. Air Force, McClellan Air Force Base

Example 5: Use of Neutron Radiography to Detect Corrosion in Adhesive-Bonded Aluminum Honeycomb Structures.

Aluminum corrosion of aircraft surfaces has plagued both military and civilian aircraft. Identification of this corrosion has been difficult, at best, usually being detected after the corrosion has caused the part to fail. Of the nondestructive testing methods used to detect aluminum corrosion, thermal neutron radiography has proved the most sensitive method to date.

The detection of aluminum corrosion is based on the attenuation properties of hydrogen associated with the corrosion products rather than aluminum and aluminum oxide with their low attenuation coefficients. Depending on the environment, the corrosion products include aluminum trihydrates, monohydrates, and various other aluminum salts. Because the linear attenuation coefficient for aluminum is similar to that of water and about 28 times greater than that for aluminum, a 0.13 mm (0.005 in.) corrosion layer should be detectable under optimum conditions.

The sensitivity standard plate for aluminum corrosion fabricated by the Aeronautical Research Laboratories (Australia) contains corrosion products varying from 0.13 to 0.61 mm (0.005 to 0.024 in.) thick (Fig. 10).

Fig. 10 Standard plate for aluminum corrosion detection contains 0.13 to 0.61 mm (0.005 to 0.024 in.) thick corrosion products. Courtesy of R. Tsukimura, Aerotest Operations Inc.

Aluminum corrosion of honeycomb structures is complicated by the bonding adhesives that may appear similar in a neutron radiograph (Fig. 11a) (see the article "Adhesive-Bonded Joints" in this Volume). Tilting of the honeycomb structure will alleviate this problem by allowing adhesive found along the bond lines to be distinguished from the randomly distributed corrosion products (Fig. 11b).

Fig. 11 Effect of bonding adhesives on the quality of neutron radiographs obtained when checking for aluminum corrosion in honeycomb structures. Radiograph taken (a) normal to specimen surface and (b) tilted at any angle other than 90° to specimen surface. Courtesy of R. Tsukimura, Aerotest Operations Inc.

Example 6: Use of Neutron Radiography to Verify Welding of Dissimilar Materials (Titanium and Niobium).

Exotic metal welded joints are a product of the extremely cold environment of space and man's desire to explore the vast emptiness of space. For space vehicles, attitude control rockets provide the fine touch for proper vehicle alignment.

For one application, a titanium-niobium welded joint was required between the light-weight propellant tank and the nozzle section. Attempts to verify weld integrity using conventional radiography were not productive.

Thermal neutron radiography provided the image required to ensure quality welds. This defect standard weld shows the porosity at the seam and the similar thermal neutron attenuation for both titanium (Ti) and niobium (formerly known as columbium, Cb) (Fig. 12a). For comparison, the x-ray radiograph image is also shown (Fig. 12b).

Fig. 12 Comparison of thermal neutron (a) and x-ray (b) radiographs of a titanium-niobium welded joint. Courtesy of R. Tsukimura, Aerotest Operations Inc.

Example 7: Use of Neutron Radiography to Detect Core Material Still Remaining in the Interior Cooling Passages of Air-Cooled Turbine Blades.

Investment casting of turbine blades using the lost wax process results in relatively clean castings. As the demand for higher-powered turbine engines has increased, the interior cooling passages for air-cooled turbine blades have become more and more complex. Concurrently, the removal of the core material has become increasingly more difficult. Incomplete removal of the core results in restricted flow through the cooling passages and possible failure of the overheated blade.

Previously, visual inspection was the nondestructive inspection method of choice for residual core detection. However, current designs preclude the use of borescopes and other visual means for the interior passages. X-radiography has proved rather ineffective in detecting residual core material. Thermal neutron radiography is the nondestructive testing method of choice, especially when gadolinium oxide (Gd_2O_3) is used to dope the core material (1 to 3% by weight) (Fig. 13) prior to casting the blade.

Fig. 13 Residual core material in a gas-cooled aircraft-engine turbine blade as detected by thermal neutron radiography. The excess core material, tagged with 1.5% Gd_2O_3 , is shown circled in the second photo from the right. Courtesy of R. Tsukimura, Aerotest Operations Inc.

When concerns about the possible detrimental effects of Gd_2O_3 during the casting process prevents its use in the core material, a procedure was developed to tag the residual core material after the core removal process. The castings are dipped in a gadolinium solution [$\text{Gd}(\text{NO}_3)_3$ in solution] to impregnate any residual core, which is then imaged and subsequently detected by neutron radiography.

The blades shown in Fig. 14 have been tagged. The neutron radiograph shows any residual core material greater than 0.38 mm (0.015 in.) in diameter. Figure 15 is a schematic of typical core fragments in investment cast turbine blades detected by thermal neutron radiography. Image clarity of gadolinium tagged or doped cores is much greater than that of normal cores.

Fig. 14 Thermal neutron radiograph of 12 turbine blades tagged with Gd_2O_3 solution. One of the 12 blades (located in the top row and second from the left) contains residual core material in its upper right-hand corner

cooling passage. Courtesy of R. Tsukimura, Aerotest Operations Inc.

Fig. 15 Schematic of turbine blade core standards: gadolinium [$\text{Gd}(\text{NO}_3)_3$ in solution] tagged core, normal core (no gadolinium tagging or doping), and Gd_2O_3 doped core. Typical core fragments of various thicknesses are shown. Source: R. Tsukimura, Aerotest Operations Inc.

Example 8: Use of Neutron Radiography to Verify Position of Explosive Charges and Seating of O-Ring Seals in Explosive Bolt Assemblies.

There are many critical applications of explosive release devices in aircraft, space, and missile systems. Nondestructive testing is an important step in the quality control portion of the production cycle for these units. Thermal neutron radiography has proved an indispensable tool in the nondestructive testing arsenal, particularly for thick-walled, metal devices, such as explosive bolts (Fig. 16).

Fig. 16 Schematic showing location of critical components that comprise an explosive bolt. Source: R. Tsukimura, Aerotest Operations Inc.

The inner details of explosive bolts can be imaged only by thermal neutron radiography methods (Fig. 17). This particular type of bolt from a missile system is activated from the bottom by actuating the firing pin onto the primer. The short section of mild detonating cord carries the energy to the output charge, which fractures the bolt and allows the bolt to be severed.

Fig. 17 Thermal neutron radiograph showing two sample bolts identical to the workpiece shown schematically in Fig. 16. Courtesy of R. Tsukimura, Aerotest Operations Inc.

In addition to the explosive charges, the internal O-ring seals, including the concentric pair around the firing pin and for the body are readily visible. For safety's sake, determining the presence of the shear pin can also be accomplished through the use of thermal neutron radiography.

Example 9: Application of Neutron Radiography to Determine Potting Fill Levels in Encapsulated Electronic Filters.

Electronic filters are an integral component of all space and satellite systems. Because the cost of these satellites is very high and the cost to repair them even more prohibitive, high reliability filters are necessary.

A common mode of filter failure is that caused by inadequate potting of the internal components and the subsequent physical breakdown of the filter during periods of high vibration, such as that encountered during vehicle launch. Thermal neutron radiography is the method of choice for determining potting fill levels in encapsulated filters.

The potting material attenuates the thermal neutrons and appears as the light density area. Voids in the potting material, the fill level, and the distribution can readily be detected with neutron radiography.

Thermal Inspection

Grover Hardy, Wright Research and Development Center, Wright-Patterson Air Force Base; James Bolen, Northrop Aircraft Division

Introduction

THERMAL INSPECTION comprises all methods in which heat-sensing devices are used to measure temperature variations in components, structures, systems, or physical processes. Thermal methods can be useful in the detection of subsurface flaws or voids, provided the depth of the flaw is not large compared to its diameter. Thermal inspection becomes less effective in the detection of subsurface flaws as the thickness of an object increases, because the possible depth of the defects increases.

Thermal inspection is applicable to complex shapes or assemblies of similar or dissimilar materials and can be used in the one-sided inspection of objects. Moreover, because of the availability of infrared sensing systems, thermal inspection can also provide rapid, noncontact scanning of surfaces, components, or assemblies.

Thermal inspection does not include those methods that use thermal excitation of a test object and a nonthermal sensing device for inspection. For example, thermally induced strain in holography or the technique of thermal excitation with ultrasonic or acoustic methods does not constitute thermal inspection.

Thermal Inspection

Grover Hardy, Wright Research and Development Center, Wright-Patterson Air Force Base; James Bolen, Northrop Aircraft Division

Principles of Thermal inspection

The basic principle of thermal inspection involves the measurement or mapping of surface temperatures when heat flows from, to, or through a test object. Temperature differentials on a surface, or changes in surface temperature with time, are related to heat flow patterns and can be used to detect flaws or to determine the heat transfer characteristics of a test body. For example, during the operation of a heating system, a hot spot detected at a joint in a heating duct may be caused by a hot air leak. Another example would be a hot spot generated when an adhesive-bonded panel is uniformly heated on one side. A localized debonding between the surface being heated and the substructure would hinder heat flow to the substructure and thus cause a region of higher temperature when compared to the rest of the surface. Generally, the larger the imperfection and the closer it is to the surface, the greater the temperature differential.

Heat Transfer Mechanisms. Heat will flow from hot to cold within an object by conduction and between an object and its surroundings by conduction, convection, and radiation. Within a solid or liquid, conduction results from the random vibrations of individual atoms or molecules that is transferred via the atomic bonding to neighboring atoms or molecules. In a gas, the same process occurs but is somewhat impeded by the greater distance between the atoms or molecules and the lack of bonds, thus requiring collisions to transfer the energy. When a gas or liquid flows over a solid, heat is transferred by convection. This occurs from the collisions between the atoms or molecules of the gas or liquid with the surface (conduction) as well as the transport of the gas or liquid to and from the surface. Convection depends upon the velocity of the gas or liquid, and cooling by convection increases as the velocity of the gas or liquid increases.

Radiation is the remaining mechanism for heat transfer. Although conduction and convection are generally the primary heat transfer mechanisms in a test object, the nature of thermally induced radiation can be important, particularly when temperature measurements are made with radiation sensors.

Electromagnetic radiation is emitted from a heated body when electrons within the body change to a lower energy state. Both the intensity and the wavelength of the radiation depend on the temperature of the surface atoms or molecules. For a blackbody, the radiation wavelength and spectral emission power vary as a function of temperature, as shown in Fig. 1. At 300 K (27 °C), the temperature of a warm day, the dominant wavelength is 10 μm (400 $\mu\text{in.}$), which is in the infrared region (Fig. 2). A surface would have to be much hotter for the dominant wavelength to fall in the visible region below

0.7 μm (30 $\mu\text{in.}$). Examples of this are red-hot steel in a forge, a light bulb filament, and the sun (indicated as solar radiation in Fig. 1 at a temperature of 5800 K). However, most subjects in thermal inspection methods will be at temperatures near room temperature and will emit in the infrared region.

Fig. 1 Spectral blackbody emissive power

Fig. 2 Spectrum of electromagnetic radiation

Material Heat Transfer Characteristics. The heat transfer mechanisms of conduction, convection, and radiation are affected by material heat transfer characteristics, and thermal inspection depends on local variations in the material heat transfer characteristics. The material characteristics that affect conduction and convection are as follows:

- Specific heat, c , is the amount of heat a mass of material will absorb for a given temperature interval
- Density, ρ , is the mass per unit volume of the material
- Thermal conductivity, k , is the amount of heat that flows in a given direction when there is a temperature difference across the material in that direction
- Thermal diffusivity, α , is the speed at which the heat flows away from a region of higher temperature to the surrounding material
- Convection heat transfer coefficient, h , is a measure of how efficiently heat is exchanged between a surface and a flowing gas or liquid
- Temperature, T , is a measure of the heat energy (local thermal agitation) contained at each point in the test object

Thermal inspection depends on differences in these material characteristics to establish a measurable, and usually localized, temperature differential. For example, when a test body with variations in density and specific heat is heated or cooled from a state of uniform temperature, the change in temperature will occur more slowly in the regions with a higher density and/or specific heat. This difference in the rate of change of temperature within the body produces temperature differentials, which may be measurable.

The important material characteristic in radiation heat transfer is the emissivity, ϵ , of a test surface. The emissivity indicates the efficiency of a surface as a radiator (or absorber) of electromagnetic radiation. Blackbodies, the most efficient radiators and absorbers of electromagnetic radiation, have an emissivity of 1.0. All other bodies have an emissivity less than 1.0.

Emissivity is a function of several variables, including color and surface roughness. Like other material heat transfer characteristics, variations in emissivity are important in thermal inspection. This is particularly true when surface temperatures are measured with infrared sensors. Variations in emissivity change the power of radiation emitted at a given temperature and thus affect infrared temperature measurements.

Thermal Inspection

Grover Hardy, Wright Research and Development Center, Wright-Patterson Air Force Base; James Bolen, Northrop Aircraft Division

Surface Preparation

The surface condition of the test object is important for thermal inspection. Inspection results can be influenced by variations in surface roughness, cleanliness, foreign material (such as decals), and the uniformity and condition of paint or other surface coatings. A good practice is to clean the surface, remove or strip poorly adhering coatings (if present), and then apply a uniform coating of readily removable flat-black paint. This will allow uniform heat transfer into (or from) the subject and will also produce a reasonably uniform emissivity.

Thermal Inspection

Grover Hardy, Wright Research and Development Center, Wright-Patterson Air Force Base; James Bolen, Northrop Aircraft Division

Establishing Heat Flow

In thermal inspection, the test object can be classified as either thermally active or thermally passive. Thermally active test objects generate the necessary heat flow during their operation, while thermally passive test objects require an external heat source or heat sink.

Thermally Active Test Objects. Some test objects can be inspected without the application or removal of heat because they are involved in a process that either generates or removes heat. When a defect results in an abnormal temperature distribution on the surface, no external heating or cooling is required. When the heat transfer process is transient, the timing of the inspection is important. An example of this would be a fluid-contaminated honeycomb panel on an aircraft that has just landed after a long flight at high altitudes. Although the entire aircraft would be warming up from the cooler temperatures experienced at high altitude, the contaminated regions would not warm as rapidly as the uncontaminated areas and therefore could be detected as cool spots in the structure if the inspection were performed immediately after landing. However, if the inspection were delayed, the entire structure would reach an equilibrium temperature, and the contaminated regions would no longer be detectable.

When the heat transfer process is in a steady-state condition, timing no longer becomes critical. An example is an electronic circuit board. Defective electronic components, in which the defect changes the electrical resistance of the component, will be either hotter or cooler than the same component properly operating on another circuit board. Another example would be a blocked tube in a heat exchanger. Temperatures along the tube would be different from temperatures along adjacent, unblocked tubes.

Thermal Excitation of Passive Test Objects. Thermally passive test objects require an external heat source or heat sink to establish the flow of heat to or from the test object. Generally, infrared or thermal measurement techniques become more sensitive as the average temperature of the subject increases. Consequently, the most common form of excitation is heating. However, in cases where additional heating could cause damage, cooling is used to create the required heat flow.

Precautions. One primary concern in heating or cooling the test object is that the thermal changes must not be intrusive. The rate of heating or cooling must be below the point of producing damaging thermal stresses. For example, a chilled glass placed in hot water may crack because the exterior is expanding rapidly while the interior is still cool and because the induced mechanical stress is sufficient to cause fracture. The degree of heating of metals must be controlled so as not to affect the heat treatment, and excessive heat can degrade the material properties of adhesives and matrices in reinforced resin composites.

Point heating can be generated with either a laser or a spherically focused infrared or visible light source to apply heat to a very localized area. For a very thin, homogeneous subject, the heat will flow outward in a circle, and the temperature

change will be inversely proportional to the square of the distance from the center of the circle or the irradiated point. For a very thick, homogeneous subject, the heat can also flow in the thickness direction; consequently, the temperature change will be inversely proportional to the cube of the distance to the point of irradiation. Most subjects are somewhere between these two extremes. Because of the rapid change in temperature across the subject, the use of point heating requires rapid-response, continuous time-based measurements, which may be enhanced with pulsed heating techniques (Ref 1, 2, 3).

Line heating is similar to point heating and is usually accomplished with a linear heat source such as a quartz-tube lamp or other heat source with a reflector that concentrates the heat into a line on the surface of the test object. For a thin panel, the heat will flow away from the line on both sides, and the temperature change will be inversely proportional to the distance from the line. For a very thick, homogeneous subject, the temperature change will be inversely proportional to the square of the distance to the line of irradiation. Because the temperature changes rapidly with distance, line heating should be monitored with rapid-response, continuously monitored, time-based equipment (tracking the time to reach a given temperature by scanning the detector outward from the line source). Another technique involves scanning the linear heat source across the surface.

Area heating typically involves uniform heating on one surface of the test object. A bank of quartz heaters, a hot plate with a high thermal conductivity material such as copper as a face sheet, or other similar devices can be used as area heaters. If heat is applied to the same side of the object that is subsequently monitored for temperature differences, the heat source is usually switched off to prevent interference with the detector from the source. If the opposite surface is heated, the heat source usually will not interfere with the temperature sensor and can be left on to provide a steady-state condition. The heat source can also be switched off to produce a transient measurement condition.

Vibration-Induced Heating. Exciting a specimen on a shaker table or with a high-power speaker will cause the specimen to respond with its natural modes of vibration. These vibrations will induce localized areas of stress and strain in the object. An anomalous area will respond differently to these induced stresses and, as a result, may be hotter or cooler than the surrounding areas if the anomaly is not at a vibration node (Ref 4, 5, 6).

Mechanically Induced Heating. Mechanically loading the specimen will cause heating in those areas that are plastically deformed. Because deformation of the specimen is normally destructive (except in those cases where deformation is part of the intended processing), mechanically induced heating is probably best suited to research studies. Examples are investigations of fatigue and crack growth, analysis of the response of a component to loading, and optimization of deformation processes such as forging (Ref 7, 8, 9).

Electrically Induced Heating. Passing current through a specimen, or inductive heating, can be applied only to materials that are electrically conductive. The heat produced is a product of the square of the electrical current and the resistance. If the anomaly of interest locally changes the electrical resistance, the local current flow and the local temperature will also change. One shortcoming of this method is that electrically conductive materials often have good thermal conductive properties, thus making the local changes in temperature short in duration (Ref 10).

Area cooling can be used when heating may be damaging or impractical. Partial immersion of a test object in a cold fluid such as ice water or liquid nitrogen may provide sufficient heat flow to reveal anomalous areas when monitoring the surface temperature as the specimen cools or returns to ambient. As with area heating, a steady-state temperature profile obtained by continued cooling of one surface of the specimen may be useful. For example, filling a cooler with ice and water would allow the exterior detection of cold spots caused by faults in the insulation or a defective lid seal.

Total immersion of the test object in a cold fluid can also be considered a cooling method. In this case, the transient surface temperatures are monitored while the test object returns to ambient temperature.

Cold-thermal-wave excitation involves preheating the test object, followed by cooling with an air jet (see Example 2). The cold-thermal-wave approach is attractive for the thermal testing of metallic structures for a number of reasons. It is an inexpensive technique for fast thermal stimulation of large areas; preheating can be performed with low-rate elements such as hot-wire heaters, although in several on-line applications the part may already be above ambient temperature; and finally, the use of a cold thermal source eliminates self-emission noise problems.

Thermal Inspection

Grover Hardy, Wright Research and Development Center, Wright-Patterson Air Force Base; James Bolen, Northrop Aircraft Division

Thermal Inspection Equipment

The temperature sensors used in thermal inspection can be separated into two categories: noncontact temperature sensors and contact temperature sensors. Other equipment includes recording instruments and calibration sources.

Noncontact Temperature Sensors

Noncontact temperature sensors depend on the thermally generated electromagnetic radiation from the surface of the test object. At moderate temperatures, this energy is predominately in the infrared region. Therefore, noncontact measurements in thermal inspection primarily involve the use of infrared sensors.

Infrared imaging equipment is available with a wide range of capabilities. The simplest systems are responsive to the near-infrared portion of the optical spectrum. These include night-vision devices and vidicon systems with silicon or lead sulfide sensors (Ref 11). Silicon sensors provide sensitivity for temperatures above 425 °C (800 °F), while lead sulfide sensors respond to temperatures above 200 °C (400 °F).

Hand-held scanners are portable imaging systems capable of responding in the far-infrared portion of the optical spectrum (wavelengths of 8 to 12 μm). This range is emitted by objects at or near room temperature. In general, hand-held scanners have poor imaging qualities and are not suitable for the accurate measurement of local temperature differences. However, they can be useful for detecting hot spots, such as overheated components, thermal runaway in an electronic circuit, or unextinguished fires (Ref 11).

High-resolution infrared imaging systems are required for most part inspection applications. These systems use either pyroelectric vidicon cameras with image-processing circuitry or cryogenically cooled mechanical scanners to provide good-quality image resolution (150 pixels, or picture elements, per scan line) (Ref 11) and temperature sensitivity to 0.1 °C (0.2 °F) (Ref 12). One system is claimed to have a temperature resolution of 0.001 °C (0.002 °F) (Ref 12). In

addition to good image resolution and temperature sensitivity, response times of the order of 0.1 s or less facilitate the detection of transient temperature changes or differentials. These imaging systems will use either a gray scale or a color scale correlated to temperature ranges to depict the temperature distribution within the image.

Thermal wave interferometer systems combine modulated laser excitation with rapid phase and amplitude sensing that can be scanned across a surface to produce an image (Ref 1, 12). One application for this type of system is the inspection of plasma-sprayed coatings. The system senses the interaction between the thermal waves of the laser and the thermal variations from coating defects and thickness variations.

Radiometers and pyrometers are devices for measuring radiation, or spot or line temperatures, respectively, without the spatial resolution needed for an imaging system. Radiometers, because they usually have slow response times, are most useful for monitoring constant or slowly varying temperatures. Pyrometers are used as noncontacting thermometers for temperatures from 0 to 3000 °C (32 to 5400 °F). Newer instruments can superimpose a line trace of the temperature on the visible-light image of the surface or scene being viewed (Ref 13). Radiometers and pyrometers are usually rugged, low-cost devices that can be used in an industrial environment for the long-term monitoring of processes.

Contact Temperature Sensors

Contact temperature sensors include material coatings and thermoelectric devices. Material coatings are relatively low in cost and simple to apply, but they may have the disadvantage of providing qualitative temperature measurements (the exception is coatings with liquid crystals, which can be calibrated to show relatively small changes in temperature). Another disadvantage of coatings is that they may change the thermal characteristics of the surface.

Cholesteric liquid crystals are greaselike substances that can be blended to produce compounds having color transition ranges at temperatures from -20 to 250 °C (-5 to 480 °F) (Ref 13). Liquid crystals can be selected to respond in a temperature range for a particular test and can have a color response for temperature differentials of 1 to 50 °C (2 to 90 °F) (Ref 13). When illuminated with white light while in their color response range, liquid crystals will scatter the light into its component colors, producing an iridescent color that changes with the angle at which the crystals are viewed. Outside this color response range, liquid crystals are generally colorless. The response time for the color change varies from 30 to 100 ms (Ref 13). This is more than adequate to allow liquid crystals to show transient changes in temperature (Ref 14). The spatial resolution obtainable can be as small as 0.02 mm (0.0008 in.) (Ref 14). In addition, because the color change is generally reversible, anomalies can be evaluated by repeating the test as many times as needed.

Techniques for applying liquid crystals are relatively straightforward once the proper blend of compounds is selected. Because liquid crystals function by reflecting light, they are more readily seen when used against a dark background. Therefore, if the specimen is not already dark, covering the surface with a removable, flat-black coating is strongly recommended before application. The crystals can then be applied by pouring, painting, spraying, or dipping. Care must be taken that the specimen or the coating is not attacked by the solvent base used with the liquid crystals. The applied film of liquid crystals must be of uniform thickness to prevent color irregularities caused by thickness differences rather than temperature differences. A good film thickness is about 0.02 mm (0.0008 in.) (Ref 13). Successive layers used to build up the film thickness should not be allowed to dry between coats. A coating of proper thickness will have a uniform, low-gloss appearance when viewed with oblique illumination.

Thermally quenched phosphors are organic compounds that emit visible light when excited by ultraviolet light. The brightness of a phosphor is inversely proportional with temperature over a range from room temperature to about 400 °C (750 °F), as indicated in Fig. 3. Some phosphors exhibit a change in brightness of as much as 25%/°C (14%/°F). An individual phosphor should be selected to cover the temperature range used for a particular inspection. The coating is applied by painting a well-agitated mixture of the phosphor onto the surface to a thickness of about 0.12 mm (0.0047 in.).

Fig. 3 Relative brightness of four thermally quenched phosphors (U.S. Radium Radelin phosphor numbers) as a function of temperature

Other Coatings. Heat-sensitive paints, thermochromic compounds, heat-sensitive papers, and meltable frosts and waxlike substances can also be used to indicate surface temperatures. These coatings are useful for determining when a surface has exceeded a certain temperature. A few of the coatings, such as the photochromic paints and thermochromic compounds, have reversible changes that can be used to evaluate indications by retesting. Each of the coatings can be applied directly to the surface. After some experimentation, the coatings could be used for specialized thermal inspections.

Thermoelectric devices are widely used for measuring temperature. Typical thermoelectric devices are thermocouples, thermopiles, and thermistors.

Thermocouples consist of a pair of junctions of two different metals. As the temperature of one of the junctions is raised, an electromotive force (voltage) relative to the other (reference) junction is produced that is proportional to the temperature difference between the two junctions. Thermocouples are usually used in a bridge circuit, with the reference junction maintained at a known and stable temperature. Thermocouples can be placed in contact with the surface of the subject or can be used near the surface to measure the air temperature.

Thermopiles are multiple thermocouples used electrically in series to increase the output voltage. Although thermopiles have a greater output (resulting in greater sensitivity) than individual thermocouples, they also have a slower response time because of the increased mass. Thermopiles are used as a sensing element in radiometers.

Thermistors are electrical semiconductors that use changes in electrical resistance to measure temperature. Thermistors are usually used in a bridge circuit, with one of the thermistors maintained at a known and stable temperature.

Recording Equipment

When high-resolution imaging systems are used, recording equipment, such as a videotape recorder, is extremely useful for analyzing transient effects or for reviewing techniques. Videotape recordings showing the time-varying response of a location on the specimen can be used to estimate the size and depth of the anomalies (Ref 2, 5, 15). Such recorded data can be processed with digital data-processing techniques to enhance the detection of temperature differences and to suppress spurious noise signals (Ref 4) (see the section "Digital Image Enhancement" in this article). Photographic techniques can also be used to record the thermal images of specimens.

When coatings are used, the recording equipment usually consists of color photographs of liquid crystals, heat-sensitive paints, thermochromic materials, and wax sticks. Black-and-white photographs are adequate for most heat-sensitive papers, melting paint materials, and thermally quenched phosphors. For time-based measurements with liquid crystals, a video recorder can provide an excellent recording of color changes as the test progresses. The recording equipment for thermoelectric devices is usually time-based chart recorders or digital recorders.

Temperature Calibration Sources

Temperature calibration sources are needed for all devices used to measure temperatures. Some systems have built-in or internal calibration sources. External sources can vary from very simple devices, such as a container of ice and water or boiling water, to thermocouple-controlled heated plates that can be adjusted to the desired temperature.

Thermal Inspection

Grover Hardy, Wright Research and Development Center, Wright-Patterson Air Force Base; James Bolen, Northrop Aircraft Division

Inspection Methods

Steady-state methods are used to detect anomalies where temperatures change very little with time. Many of the thermally active objects or processes can be observed under steady-state conditions. For example, a steam line that regularly carries steam can be inspected for insulation defects by looking for hot spots. These types of anomalies usually produce large differences in temperature, and the resultant images or contact coating indications are easily interpreted.

Steady-state methods are more challenging with the thermal excitation of passive objects. Uniform heating and cooling are essential, and the heating and cooling rates must be adjusted to allow the temperature differences caused by the defects to be maintained. A honeycomb panel can be inspected for liquid intrusion or disbonds by heating one side and cooling the opposite side. The cooled side is viewed for the inspection, and either infrared imaging or contact coatings can be used. Areas of liquid intrusion will produce warmer temperatures than the surroundings, while disbonds will produce cooler temperatures.

In general, anomalies must be large, must be close to the surface, or must create large temperature differences to be detectable with steady-state methods. With active heating or cooling, steady-state measurements will be more effective when made on the surface where the heat transfer is by convection.

Time-based methods are used to detect anomalies where temperatures change during the inspection. Temperature differences may develop and then disappear as a subject changes from one overall temperature to another (Ref 2, 15). The change may be actively or passively produced. For example, a hot forging exiting a forging press or die will cool to room temperature and will produce a temperature difference at a forging lap for only a short time. An aircraft structure with hidden corrosion can be actively heated from one side and then allowed to cool. Areas with trapped water will cool more slowly and create a temporary warm spot, while thinned or corroded areas will cool slightly faster than the rest of the structure and produce a temporary cool spot.

In general, time-based methods can provide the maximum detection sensitivity and can permit inspection from one side. For infrared or photothermal imaging methods utilizing active heating, inspection can be performed after the heat source is turned off, thus eliminating the interference in the image from the heat source itself. Multiple time-based measurements are required for quantitative interpretation of thermal images (Ref 5). For example, a video recording will capture transient temperature differences produced with surface coating methods on a continuous basis and can be analyzed frame by frame to evaluate the indications as they appear and disappear.

Image interpretation has proved to be the most difficult part of many thermal inspection applications. Strong indications with large temperature differences are the easiest to interpret. Strong indications will usually provide a truer image of the anomaly than weak indications. An anomaly close to the surface will produce a stronger indication than an identical anomaly far from the surface, and the resultant indication will more accurately portray the size and shape of the source.

Thermal images reflect the heat flow in the structure. If the structure has an area with a subsurface support or cavity, the heat will flow faster or slower, respectively, into these areas. The edges of the structure will experience more convective and radiative heat transfer than the remainder. Support of the structure will also affect the image because the support is usually another source of heat transfer.

Thermal images can also be influenced by other factors. The heating source, as well as nonuniformities in the emissivity of the specimen caused by variations in surface roughness and color, can produce indications. Consequently, the first step in image interpretation is to look at the strength of the image and closely examine the surface and structure of the specimen as well as the uniformity of the heating source. When no obvious surface or structural correlation exists between the specimen and the image, an internal anomaly should be suspected. If available or possible, digital image enhancement, such as filtering, image averaging, or reference image subtraction, should be used to eliminate nonrelevant indications. An indication that persists is probably a valid indication of an anomaly.

Digital image enhancement can be used to improve the quality of thermal images. Spatial filtering can be used to smooth the temperature data by eliminating the high-frequency noise caused by heating devices and external sources. One technique involves mathematically replacing each pixel value with the average value of its four nearest neighbors (Ref 4). Signal-averaging techniques can also be used to reduce measurement noise if the image does not vary too rapidly with time. Averaging individual pixel values from 100 successive image frames will eliminate 90% of the noise and will increase sensitivity (Ref 4).

Space-domain and time-domain subtraction functions can also be used to enhance flaw detection. Space-domain subtraction functions can eliminate temperature differentials from repetitive sources of noise (such as local variations in surface emissivity), patterns resulting from a nonuniform (or line or spot) heat source, and local variations in heat loss unrelated to anomalies (such as convection patterns or conduction into supporting structures). If self-referencing is not possible, a defect-free reference specimen with similar characteristics can be used to provide a reference image in a space-domain subtraction algorithm (Ref 15). For example, an image taken when a component is new or when a process is functioning properly can be subtracted from an image taken at a later date to indicate damage, flaw propagation, or changes in the process (Ref 4).

When the thermal noise is not repetitive (as when surface emissivity is unpredictable or when reflections occur from an unknown background source), time-domain subtraction functions can enhance flaw detection. A graphic example of time-domain image subtraction is shown in Fig. 4. An irregular pattern of reflective noise from an infrared heat source was

eliminated by subtracting two images obtained 3 s and 5 s after initial heating to reveal a defect in a graphite epoxy sheet (Ref 15).

Fig. 4 Example of time-domain image processing. (a) Image over a defect (10 × 10 mm and 0.5 mm deep, or 0.4 × 0.4 in. and 0.2 in. deep) obtained 3 s after initial heating. (b) Image over the same defect obtained 5 s after initial heating. (c) Image of defect after subtracting image (a) from image (b). Courtesy of P. Cielo, National Research Council of Canada

Thermal Inspection

Grover Hardy, Wright Research and Development Center, Wright-Patterson Air Force Base; James Bolen, Northrop Aircraft Division

Quantitative Methods

In general, thermographic methods do not lend themselves to the rapid derivation of quantitative data on anomalies. One exception is the case of thin coatings, in which anomaly size and shape correspond very closely to the size and shape of infrared images or contact coating indications from optimized inspections. Similarly, quantitative estimates of very thin coating thicknesses are possible with proper time-based techniques (Ref 1).

Quantification of anomaly size following the detection by thermal methods is usually more readily accomplished by application of a second nondestructive evaluation (NDE) method. For example, determining the size and depth of a delamination detected in a graphite/epoxy laminate by thermal methods would be best achieved by ultrasonic techniques. A crack detected in a rocket propellant tank would be best quantified by other methods, such as multiple x-ray films or x-ray computer-aided tomography.

There are some cases in which quantification from thermal indications is always desirable. For example, in a process producing hot specimens, rapid feedback may be necessary because time is too short to wait for the specimens to cool for

a subsequent inspection. Another example would be a coating process that needs a rapid thickness measurement to ensure proper thickness.

Most quantitative methods are still under development. Nearly all the quantification methods must be tailored to specific applications. Although some methods can be approached from a theoretical basis, most require an empirical development effort involving reference standards, multiple timebased measurements, and interpretive methods or rules (Ref 5, 13).

Reference standards are as necessary for thermal methods as they are for other NDE methods. Standards ensure consistent performance of the thermal activation methods and the temperature-sensing materials or equipment. Reference standards are essential for quantitative techniques.

A reference standard should closely represent the thermal and surface characteristics of the components or items inspected. For example, if the subject is a solder joint, the reference should be a solder joint with the same contact area, heat sink, wire sizes, and other characteristics. The standard must also provide an anomaly-free condition and a second unacceptable condition associated with a size or the presence of an anomaly. A standard for quantitative methods requires a progression of anomaly sizes and locations. The standard needs to cover the potential accept/reject conditions that can exist in the components to be inspected. This typically necessitates a test program to establish the anomaly sizes and locations that are unacceptable for proper operation of the components to be inspected (Ref 16).

Multiple time-based measurements are needed to establish correlations between a response to thermal activation and anomaly size and location (Ref 5, 16). For pulsed or modulated thermal excitation, the time delay of the temperature response can be recorded as a relative phase change, which may be related to a parameter such as coating thickness (Ref 1) or delamination depth (Ref 3). Alternatively, variations in isotherm position with time can be monitored as a function of anomaly size and depth to establish known time-based response characteristics. Figure 5 shows how the effusivity (which is a function of the pulsed heat input and the time-dependent temperature change) directly over a 20×20 mm (0.8×0.8 in.) void in a carbon-epoxy laminate varies with time for void depths of 0.3, 1.12, and 2.25 mm (0.012, 0.044, and 0.088 in.).

Fig. 5 Experimental apparent-effusivity curves, after correction, of the carbon-epoxy laminate sample in the regions with embedded defects of 20×20 mm (0.8×0.8 in.) area at three depths. A, 0.3 mm (0.012 in.); B, 1.12 mm (0.044 in.); C, 2.25 mm (0.088 in.). Source: Ref 2

Quantitative interpretation rules are needed before the time-based data can be used in an evaluation. A simple example is the phase change response as a function of coating thickness of yttria-stabilized zirconium on a nimonic substrate, as shown in Fig. 6. For an acceptable coating thickness of 0.45 to 0.6 mm (0.018 to 0.023 in.), the data show that a 0.5 Hz modulation of the thermal excitation will supply the necessary phase sensitivity and that acceptable coating

thickness will be indicated by phase angles ranging from 5 to 13°. This information then provides the accept/reject criteria for tests conducted under these conditions.

Fig. 6 Variations in the phase of temperature changes versus the coating thickness of a yttria-stabilized zirconia coating on a nimonic substrate. The phase of the temperature changes are relative to the modulation (0.5 and 5 Hz) of the thermal excitation. Source: Ref 1

For a three-variable situation in which void thickness, width and depth beneath a surface are determined, at least three time-based measurements are needed (Ref 5). The resulting calculations relating defect geometry and location are complicated and can be performed only with computer assistance.

Applications

The applications discussed below provide examples of how thermal methods have been used. For ease of discussion, the applications have been divided into the following categories:

- Hot and cold equipment
- Process control
- Liquid intrusion
- Disbonds, delaminations, and voids
- Electronic devices
- Research

Hot and Cold Equipment. Many types of equipment that conduct or generate heat during operation are likely candidates for thermographic methods. Heating ducts, steam lines (Ref 13), radiators (Ref 17), heat exchangers (Ref 15), exhaust systems/chimney stacks (Ref 13), and refrigeration systems are heat transfer devices for which thermal inspection techniques can be used during periodic inspections for leaks, clogged passages, and missing or defective insulation. Furnaces, ovens, salt baths, autoclaves, reaction stacks, and hot manufacturing equipment (such as presses and rolling mills) may also require periodic inspection for unnecessary heat losses. Thermographic techniques are also used to inspect cryogenic tanks.

Other equipment, such as bearings, slides, brakes, transmitting antennas, and electrical equipment, generates heat during operation. Localized hot areas are usually a symptom of a mechanical or electrical malfunction, and early detection provides the opportunity to replace the defective components during regularly scheduled maintenance or before more serious damage occurs.

Process Controls. Thermal inspection methods are appropriate for certain processes in which the products are above room temperature as they exit a process. Examples are heat-set and heat-shaped plastics, hot-worked metal components, hot coating processes, and weld components. Components can be monitored as they exit the process. Abnormal temperatures would indicate an out-of-control process, and corrections can be made to prevent the production of large numbers of defective parts. An example of an actively heated process control method is the technique for monitoring phosphate coating thickness using infrared absorption characteristics (Ref 18).

Liquid Intrusion. Water or fuel intrusion in honeycomb structures is a significant problem for aircraft maintenance. Inspections can be performed immediately after flight to detect such liquids as the structure warms to ambient temperature. Water intrusion in roofs can also be detected in the evening as ambient temperature drops. This method has been reported to be successful in detecting leaks and retained moisture in insulation (Ref 19). The level of fluids in a sealed tank can also be determined thermographically. This is accomplished by either heating or cooling the tank and then noting the location of a sharp differential in resulting tank temperature.

Disbonds, Delaminations, and Voids. Modern fabrication techniques rely heavily on the use of bonding for structures and protective coatings. Thermal techniques are good candidates for the detection of disbonds, delaminations, and voids in thin laminates, honeycomb to thin face sheets, and protective coatings (Ref 15). As the specimen thickness increases, thermal inspection becomes less effective because the possible depth of the defect may be greater.

Thermal inspection may also be difficult with bonded metal structures, such as adhesive-bonded aluminum. The radiative heating of aluminum is relatively inefficient because of the low surface absorptivity, and the thermal-emission signal is low because of the low emissivity. For such reasons, as well as to avoid reflective noise, the aluminum parts must normally be black-painted prior to thermal inspection. Moreover, the high thermal diffusivity of aluminum requires a high thermal-power injection to produce a visible thermal pattern before thermal uniformization is reached within the structure.

Nevertheless, the possibility of evaluating adhesive-bonded aluminum structures at the rapid pace afforded by thermal inspection is attractive, particularly for online applications (Ref 20). The following two examples describe the thermal inspection of adhesive-bonded aluminum after black-painting.

Example 1: Thermal Inspection of Adhesive-Bonded Aluminum Sheets

(Ref 15). Figure 7 shows the detection by a transmission configuration of a 1.5×1.5 cm (0.6×0.6 in.) lack-of-adhesive defect on a lap joint with nearly 1 mm (0.04 in.) thick skin. The hotter portions on the left and right of the thermal image

correspond to the single-sheet material, which was heated at a faster rate than the adhesive joint. The heating rate must be sufficiently fast to avoid significant thermal propagation from the hot single-sheet to the adhesive point. Properly shaped shading masks on the lamp side can be used to avoid single-sheet over-heating when the sample geometry is repetitive. A line heating and sample displacement configuration of the type described in Ref 21 can also be used for the fast-response testing of longitudinal joints.

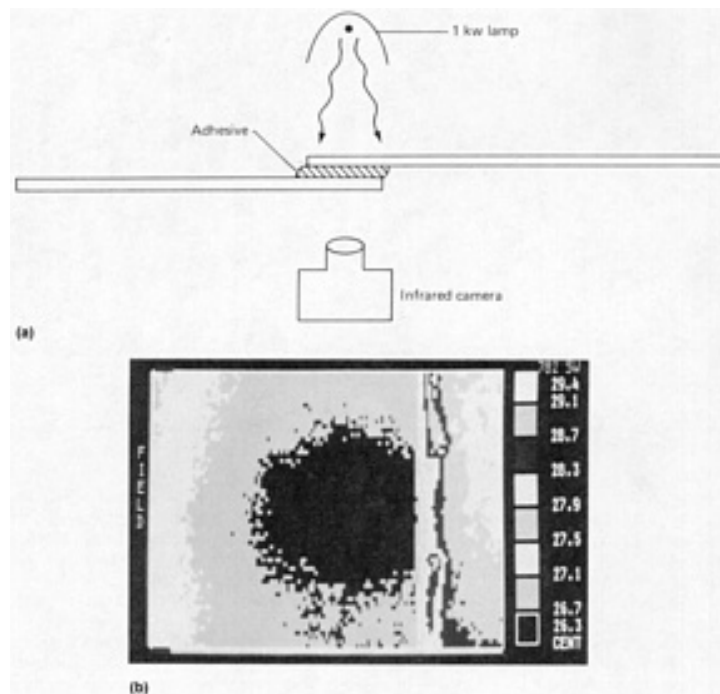

Fig. 7 Thermographic inspection of adhesive-bonded aluminum sheets. (a) Experimental configuration. (b) Thermal image of a 15 × 15 mm (0.6 × 0.6 in.) disbonding in an image area of 40 × 50 mm (1.6 × 2.0 in.). Courtesy of P. Cielo, National Research Council of Canada

Example 2: Cold-Thermal-Wave Technique for the Thermal Inspection of an Adhesive-Bonded Aluminum Structure

(Ref 15). Rapid back heating procedures are difficult to apply when analyzing complex structures of the type shown in Fig. 8. In this case, a cold-thermal-wave approach was applied by which the whole structure was previously warmed up uniformly by nearly 10 °C (20 °F) above ambient, and an ambient air jet was used to rapidly cool the inspected face. The thermal image shows a relatively warmer central area corresponding to the adhesive-bonded strip (oriented vertically in the thermograph). The cooler area in the center of the strip corresponds to a lack-of-adhesive unbond.

Fig. 8 Cold-thermal-wave technique for inspecting a preheated, adhesive-bonded aluminum structure. (a) Experimental configuration. (b) Thermal image of a 10 × 10 mm (0.4 × 0.4 in.) disbonding. Courtesy of P. Cielo, National Research Council of Canada

Electronic devices typically fail by local overheating, corrosion, or poor solder joints. Infrared microscopes have been used to inspect microelectronics for overheating, and laser-generated heat has been used to inspect circuit-board solder joints. More conventional thermal inspection methods have been used to inspect solder joints during cool-down after fabrication or during circuit operation. Solar cells have also been screened for defects with thermal techniques.

Research. Several investigators have used the heat generated by permanent deformation to track the onset of failure in tensile overloading and crack propagation in fatigue testing (Ref 7, 8, 9). Samples of components can be loaded to failure under thermographic monitoring to pinpoint the origin and propagation of deformation (Ref 7).

Optical Holography

Revised by James W. Wagner, The Johns Hopkins University

Introduction

HOLOGRAPHY is a process for creating a whole image--that is, a three-dimensional image--of a diffusely reflecting object having some arbitrary shape. More precisely, it is a means of recording and subsequently reconstructing wave fronts that have been reflected from or transmitted through an object of interest. Because the entire wave front and not just a two-dimensional image is reconstructed, an image of the original object can be viewed with full depth of field, location, and parallax.

The process involves two steps. In the first step, both the amplitude and phase of any type of coherent wave motion emanating from the object are recorded by encoding this information in a suitable medium. This recording is called a hologram. At a later time, the wave motion is reconstructed from the hologram by a coherent beam in a process that results in the regeneration (reconstruction) of an image having the true shape of the object. The utility of holography for the nondestructive inspection of materials, components, and structures lies in the fact that this reconstructed image can then be used as a kind of three-dimensional template against which any deviations in the shape or dimensions of the object can be observed and measured.

In principle, holography can be performed with any wavelike radiation encompassed in the entire electromagnetic spectrum, any particulate radiation (such as neutrons and electrons) that possesses wave-equivalent properties, and nonelectromagnetic wave radiation (such as sound waves). The two methods currently available for practical nondestructive inspection are:

- Optical holography, using visible light waves, which is discussed in this article

- Acoustical holography, using ultrasonic waves, which is discussed in the article "Acoustical Holography" in this Volume

An optical holographic system can be designed to do only one task or various tasks. A system can be purchased as a unit or assembled in-house from components, or holography can be purchased as an outside service. The selection of a system requires weighing the advantages and disadvantages of each type. The factors governing the selection of holographic systems are discussed in the Appendix to this article.

Optical Holography

Revised by James W. Wagner, The Johns Hopkins University

Uses of Optical Holographic Interferometry

Optical holographic interferometry has been successfully used both in research and testing applications as a noncontacting tool for displacement, strain and vibration studies, depth-contour mappings, and transient/dynamic phenomena analyses. Specific applications of optical holography in nondestructive evaluation include:

- Detection of debonds within honeycombcore sandwich structures
- Detection of unbonded regions within pneumatic tires and other laminates
- Detection of cracks in hydraulic fittings
- Qualitative evaluation of turbine blades

These uses and others are described in detail in later sections of this article. The advantages and disadvantages of using optical holographic interferometry for nondestructive inspection are described below.

The advantages of using optical holographic interferometry for nondestructive inspection include the following:

- It can be applied to any type of solid material--ferromagnetic or nonferromagnetic; metallic, nonmetallic, or composite; electrically or thermally conductive or nonconductive; and optically transparent or opaque
- It can be applied to test objects of almost any size and shape, provided a suitable mechanism exists for stressing or otherwise exciting the object
- Pulsed-laser techniques allow the inspection of test objects in unstable or hostile environments
- It has an inherent sensitivity to the displacement or deformation of at least one-half an optical wavelength, or about 125 nm (1250 Å). This permits the use of low levels of stress during inspection. Further, special analysis techniques can provide improved sensitivity of almost 1000-fold
- It does not rely on data acquisition by either point-by-point determinations or scanning processes; instead, three-dimensional images of interference fringe fields are obtained of the entire surface (front, back, and internal, if desired) or a large fraction thereof
- It allows flexibility of readout. For example, in flaw detection applications, the images can be examined purely qualitatively for localized fringe anomalies within the overall fringe field. If, on the other hand, the application involves the strain analysis of an object subjected to a specific type of stress, the image can be analyzed to yield a highly quantitative point-by-point map of the resulting surface displacements
- It permits comparison of the responses of an object to two different levels of stress or other excitation. The frame of reference for this differential measurement is usually, but not always, the unstressed or natural state of the test object. This differential type of measurement contrasts with absolute types, which are made without a frame of reference, and with comparative measurements, in which a similar, but different, object is used as a frame of reference
- The interferograms can be reconstructed at any later time to produce three-dimensional replicas of the

previously recorded test results

The disadvantages of using optical holographic interferometry for nondestructive inspection include the following:

- Although no physical contact with the test object is required to effect the interaction of the coherent light with either the test object or the photographic plate, it is often necessary to provide fixturing not only for the test object but also for the stressing source. The success of a holographic inspection procedure depends largely on the adequacy of design and the practical performance of both the fixturing and the stress-imparting mechanisms
- It is limited to test objects with wall or component thicknesses that will offer sufficiently large displacements without requiring stressing forces that will cause rigid-body movement or damage to the object. For sandwich structures, the thickness of the skin is the limiting factor; the maximum skin thickness that can be tested is a function of the stressing method
- Holographic methods are best suited to diffusely reflecting surfaces with high reflectivity. Removable coatings are often sprayed onto strongly absorbing materials and specularly reflecting surfaces
- Although holographic interferometry is capable of accurately locating a flaw within the surface area of the test object being inspected, the cross-sectional size of the flaw can often be only approximately determined, and information concerning the depth of the flaw, when obtainable at all, is qualitative in nature. Furthermore, a direct correspondence does not always exist between the shape of a flaw-indicative fringe anomaly and the actual shape of the flaw and between the size of the fringe anomaly and that of the flaw. For a given set of test conditions in which only the type of the applied stress is varied, the fringe anomalies indicating the presence of a flaw will vary. In many cases, flaw detection by means of holographic inspection is impeded by the appearance of spurious fringes associated with rigid-body motion and/or rigid-body displacements
- Where visual interpretation of interferograms is to be performed, holographic interferometry may be limited in its dynamic range for some applications. However, electronic methods for fringe interpretation have been used to provide increased sensitivity and dynamic range
- Test results sometimes cannot be analyzed because of the localization of the interference fringes in space rather than on the surface of the test object (in realtime holographic interferometry) or on the reconstructed image of the object (in double-exposure holographic interferometry)
- With the exception of holographic-contouring applications, holographic interferometry is currently limited to differential tests, in which the object is compared to itself after it has been subjected to changes in applied stress. Comparative tests, in which a given object can be compared to a standard object, are not feasible with holographic interferometry because of inherent random variations in test object surfaces
- Personnel performing holographic inspection must be properly trained. The greater the sophistication of the equipment, the greater the required operating skill. Because lasers are a necessary part of holographic equipment, operating personnel must adhere strictly to existing safety codes, particularly with respect to eye safety

Optical Holography

Revised by James W. Wagner, The Johns Hopkins University

Holographic Recording

When visible light waves are employed in holography, the hologram is recorded with an optical system often referred to as a holocamera (Fig. 1a). A monochromatic laser beam of phase-coherent light is divided into two beams by a variable beam splitter. One beam--the object beam--is expanded and filtered by a lens/pinhole spatial filter that reduces the effects of dirt and dust in the beam path. The expanded divergent beam is then directed to illuminate the object uniformly. A

portion of the laser light reflected from the object is intercepted by a high-resolution photographic plate, as shown in Fig. 1(a). The second beam--the reference beam--originating from the beam splitter diverges from a second spatial filter and is steered onto the photographic plate directly without reflecting from the object. With either the object beam or reference beam absent, a uniformly exposed photographic plate will result. However, with both coherent beams falling on the plate simultaneously, an interference pattern is generated as a result of the coherent interaction of the two beams, and this pattern is recorded by the photographic emulsion. In fact, this complex interference pattern recorded on the photographic plate contains all the information necessary to reconstruct an extremely high fidelity, three-dimensional image of the object.

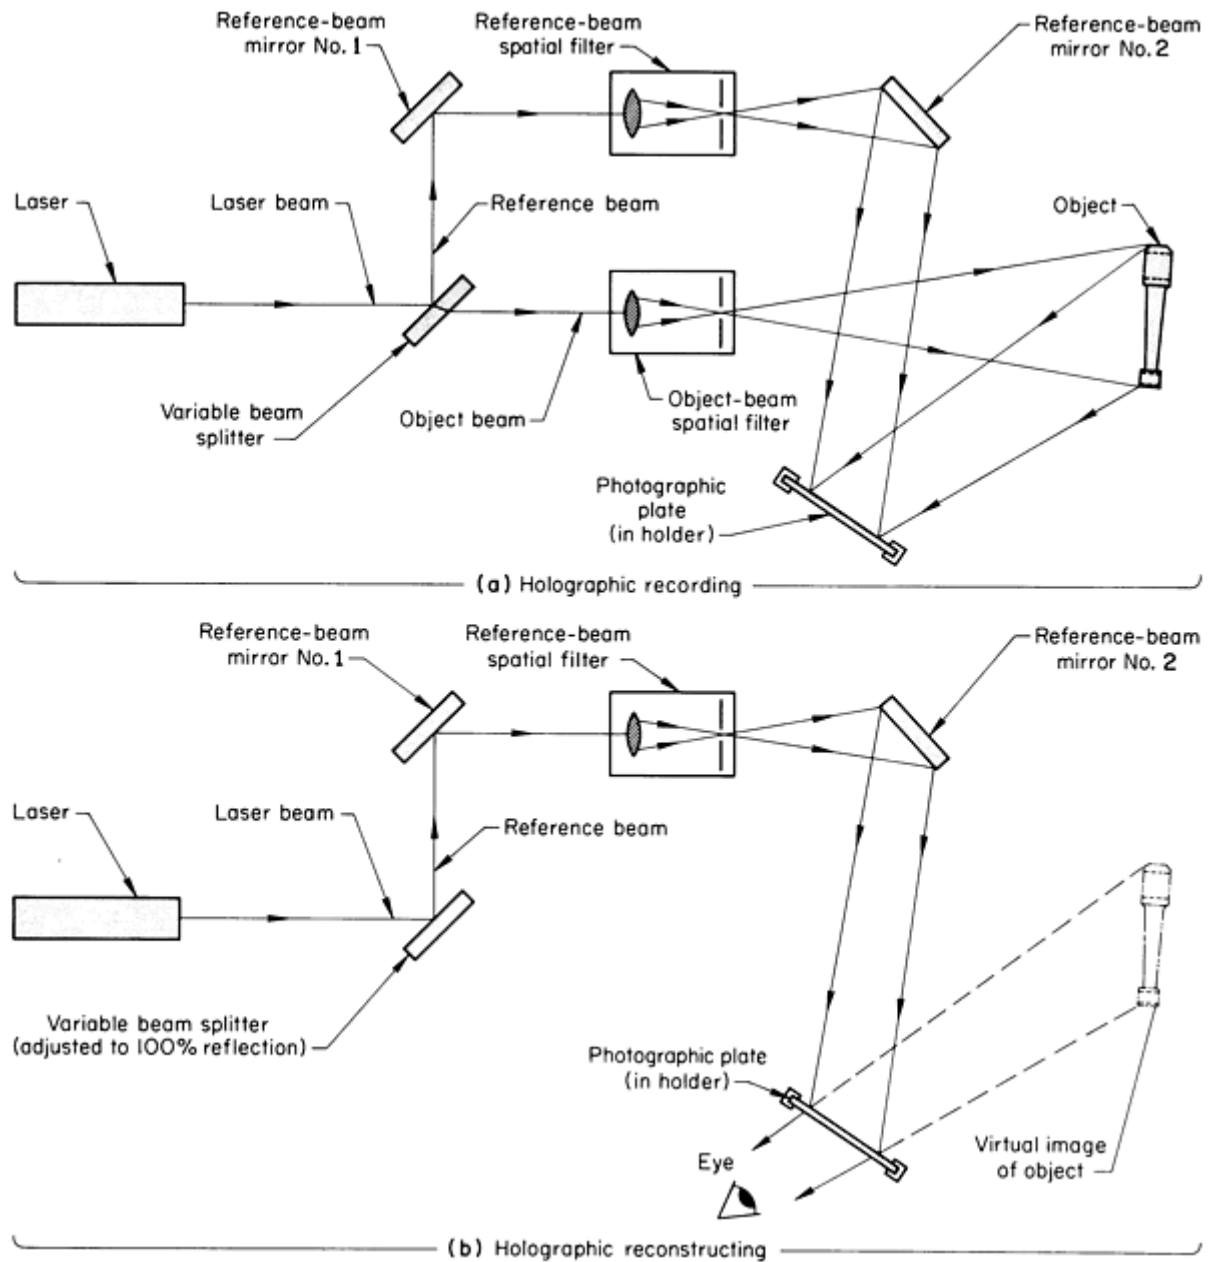

Fig. 1 Schematics of the basic optical systems used in continuous-wave holography. (a) Holocamera used to record hologram of an object on a photographic plate. (b) Optical system for reconstructing a virtual image of the object from the hologram on the photographic plate

Fine-Grain Photographic Emulsions Required for Fringe Resolution. The details of the interference pattern recorded on the film are extremely fine, requiring that high-resolution emulsions be used in very stable recording systems. The fixed wavelength of the light used and the varying magnitude of the offset angle (the angle between the object beam and reference beam at any point on the photographic plate) determine the orientation and spacing of the fringes comprising the recorded interference pattern. The fringe spacing in turn influences the resolution requirements of the

recording medium. These requirements are generally of the order of 500 to 3000 lines per millimeter. Thus, the photographic emulsion must have sufficient resolution and contrast to record these interference fringes clearly. Ordinary photographic emulsions are usually unsatisfactory, because they can resolve at most only about 200 lines per millimeter; exceptionally fine grain emulsions are required.

Optical Path Length Variations. The difference between the path lengths of the reference beam and the object beam must be less than the temporal coherence length of the laser beam and should be as close to zero as possible to obtain fringes of the highest contrast. The holocamera must be isolated from vibration to the extent that there is less than one-fourth to one-eighth wavelength variation in the object beam and reference beam path lengths during an exposure. Such variations can be caused by the relative motion of optical elements in the beam paths, by room vibration, or by temperature changes. Air turbulence can also cause optical path changes that contribute to reduced interference fringe contrast.

Reference Beam Versus Object Beam Intensity Variations. In the absence of optical path length variations, the contrast of the interference fringes is directly related to the amplitude of the reflected light from the object and the amplitude of the reference beam. Thus, when recording a hologram, the reference and object beam intensities are adjusted with a variable beam splitter and/or appropriate attenuating filters to obtain optimum contrast. Although optimum fringe contrast would be obtained for equal object and reference intensities at the film plate, the variation in reflected intensities from point to point on a diffuse object, coupled with concerns for recording linearity, dictates that the reference beam intensity be two to ten times brighter than the object beam intensity at the film plate. A more detailed discussion of the effects of this and other recording parameters is given in the section "Effects of Test Variables," (specifically the discussion "Exposure Parameters") in this article.

Continuous-Wave (CW) Lasers Versus Pulsed Lasers. Two generic classes of laser sources are available for holography: continuous-wave lasers and pulsed lasers. Continuous-wave lasers are characterized by the continuous (steady-state) emission of coherent light at relatively low power. Pulsed lasers are characterized by the pulsed emission of coherent light at relatively high power over sometimes extremely short intervals of time.

Depending on the laser power, a few seconds of exposure of a holographic plate with a CW laser can yield the same results as a single-pulse exposure with a pulsed laser with regard to achieving an exposure level suitable for reconstructing a holographic image. Therefore, a CW laser source can be effectively used to record holograms of objects that are stationary throughout the duration of the exposure. A pulsed-laser source must be used to record holograms of objects undergoing rapid changes by freezing the motion (that is, by recording information over a very small interval of time). Regardless of which class of laser source is used for recording the hologram, a CW laser is always used for reconstruction.

Optical Holography

Holographic Recording

When visible light waves are employed in holography, the hologram is recorded with an optical system often referred to as a holocamera (Fig. 1a). A monochromatic laser beam of phase-coherent light is divided into two beams by a variable beam splitter. One beam--the object beam--is expanded and filtered by a lens/pinhole spatial filter that reduces the effects of dirt and dust in the beam path. The expanded divergent beam is then directed to illuminate the object uniformly. A portion of the laser light reflected from the object is intercepted by a high-resolution photographic plate, as shown in Fig. 1(a). The second beam--the reference beam--originating from the beam splitter diverges from a second spatial filter and is steered onto the photographic plate directly without reflecting from the object. With either the object beam or reference beam absent, a uniformly exposed photographic plate will result. However, with both coherent beams falling on the plate simultaneously, an interference pattern is generated as a result of the coherent interaction of the two beams, and this pattern is recorded by the photographic emulsion. In fact, this complex interference pattern recorded on the photographic plate contains all the information necessary to reconstruct an extremely high fidelity, three-dimensional image of the object.

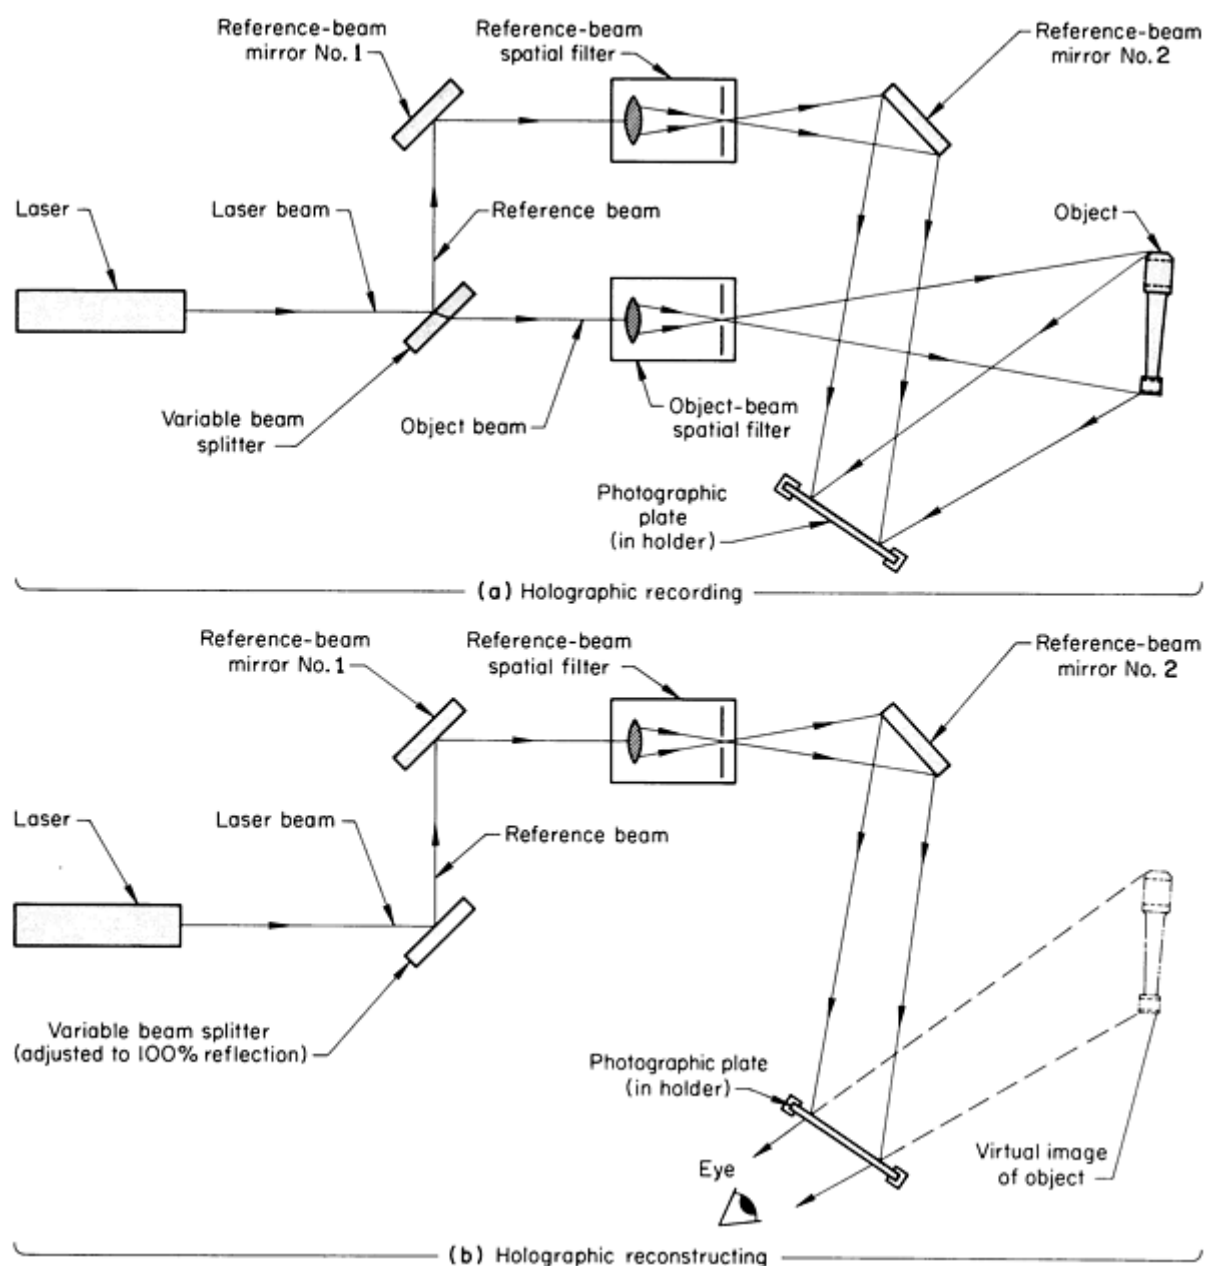

Fig. 1 Schematics of the basic optical systems used in continuous-wave holography. (a) Holocamera used to record hologram of an object on a photographic plate. (b) Optical system for reconstructing a virtual image of the object from the hologram on the photographic plate

Fine-Grain Photographic Emulsions Required for Fringe Resolution. The details of the interference pattern recorded on the film are extremely fine, requiring that high-resolution emulsions be used in very stable recording systems. The fixed wavelength of the light used and the varying magnitude of the offset angle (the angle between the object beam and reference beam at any point on the photographic plate) determine the orientation and spacing of the fringes comprising the recorded interference pattern. The fringe spacing in turn influences the resolution requirements of the recording medium. These requirements are generally of the order of 500 to 3000 lines per millimeter. Thus, the photographic emulsion must have sufficient resolution and contrast to record these interference fringes clearly. Ordinary photographic emulsions are usually unsatisfactory, because they can resolve at most only about 200 lines per millimeter; exceptionally fine grain emulsions are required.

Optical Path Length Variations. The difference between the path lengths of the reference beam and the object beam must be less than the temporal coherence length of the laser beam and should be as close to zero as possible to obtain fringes of the highest contrast. The holocamera must be isolated from vibration to the extent that there is less than one-fourth to one-eighth wavelength variation in the object beam and reference beam path lengths during an exposure. Such

variations can be caused by the relative motion of optical elements in the beam paths, by room vibration, or by temperature changes. Air turbulence can also cause optical path changes that contribute to reduced interference fringe contrast.

Reference Beam Versus Object Beam Intensity Variations. In the absence of optical path length variations, the contrast of the interference fringes is directly related to the amplitude of the reflected light from the object and the amplitude of the reference beam. Thus, when recording a hologram, the reference and object beam intensities are adjusted with a variable beam splitter and/or appropriate attenuating filters to obtain optimum contrast. Although optimum fringe contrast would be obtained for equal object and reference intensities at the film plate, the variation in reflected intensities from point to point on a diffuse object, coupled with concerns for recording linearity, dictates that the reference beam intensity be two to ten times brighter than the object beam intensity at the film plate. A more detailed discussion of the effects of this and other recording parameters is given in the section "Effects of Test Variables," (specifically the discussion "Exposure Parameters") in this article.

Continuous-Wave (CW) Lasers Versus Pulsed Lasers. Two generic classes of laser sources are available for holography: continuous-wave lasers and pulsed lasers. Continuous-wave lasers are characterized by the continuous (steady-state) emission of coherent light at relatively low power. Pulsed lasers are characterized by the pulsed emission of coherent light at relatively high power over sometimes extremely short intervals of time.

Depending on the laser power, a few seconds of exposure of a holographic plate with a CW laser can yield the same results as a single-pulse exposure with a pulsed laser with regard to achieving an exposure level suitable for reconstructing a holographic image. Therefore, a CW laser source can be effectively used to record holograms of objects that are stationary throughout the duration of the exposure. A pulsed-laser source must be used to record holograms of objects undergoing rapid changes by freezing the motion (that is, by recording information over a very small interval of time). Regardless of which class of laser source is used for recording the hologram, a CW laser is always used for reconstruction.

Optical Holography

Revised by James W. Wagner, The Johns Hopkins University

Holographic Reconstruction

In the reconstruction process (Fig. 1b), the complex interference pattern recorded on the hologram is used as a diffraction grating. When the grating is illuminated with the reference beam only, three angularly separated beams emerge: a zero-order, or undeflected, beam and two first-order diffracted beams. The diffracted beams reconstruct real and virtual images of the object to complete the holographic process. The real image is pseudoscopic, or depth inverted, in appearance. Therefore, the virtual image (also referred to as the true, primary, or nonpseudoscopic image) is the one that is of primary interest in most practical applications of holography. In Fig. 1(b), only the first-order diffracted beam that yields the virtual image has been shown; the other two beams were omitted for reasons of clarity. If the original object is three dimensional, the virtual image is a genuine three-dimensional replica of the object, possessing both parallax and depth of focus. However, if the configuration of the optical system or the wavelength of light used during reconstruction differs from that used during recording, then distortion, aberration, and changes in magnification can occur. (The holographic recording and reconstruction systems can be designed to minimize these effects.)

The light intensity in the reconstructed image depends on the diffraction efficiency of the hologram. This efficiency is a function of several recording parameters, the most significant of which is the type of recording medium (film) used. Under ideal conditions, gelatin or polymeric films, which modify only the phase of the reconstructing light without absorbing it, can provide nearly 100% holographic diffraction efficiency. Commercially available holocameras using thermoplastic phase holograms, which can be developed by a thermal process without removing the film from its holder, provide diffraction efficiencies up to about 20%. High-resolution black-and-white film plates, which are used to form absorption holograms, have theoretical efficiencies up to 6.25%. For a typical hologram of this type, however, the intensity is usually less than 3% of the incident reconstructing light intensity.

Once reconstructed, the light in the image beam can be used just as one would use the light from an illuminated object viewed through a window. Pictures of the reconstructed image can be recorded photographically or electronically.

Interferometric Techniques of Inspection

When optical holography is applied to the inspection of parts, the generation of a three-dimensional image of the object is of little value. Furthermore, for opaque materials, optical holography is strictly limited to surface observations. Therefore, if optical holography is to be implemented for nondestructive evaluation and inspection, supplementary means must be used to stress or otherwise excite test objects so as to produce surface manifestations of the feature of interest. It is for the measurement of such manifestations that the techniques of optical holography have been further developed to form the subfield of holography termed optical holographic interferometry.

As in conventional interferometry, holographic interferometric measurements can be made with great accuracy (to within a fraction of the wavelength of the light being used). Although conventional interferometry is usually restricted to the examination of objects possessing highly polished surfaces and simple shapes, holographic interferometry can be used to examine objects of arbitrary shape and surface condition. Because holographic interferometry produces a three-dimensional fringe-field image, which can be examined from many different perspectives (limited only by the size of the hologram), a single holographic interferogram is equivalent to a series of conventional two-dimensional interferograms.

As with conventional interferometry, holographic interferometry is the comparison of a test wave front with a known master wave front. Deviations of the test wave front from the master result in the appearance of interferometric fringes. In contrast to conventional interferometry, in which the master wave front is generated by appropriate imaging optics and mirrors, holographic interferometry systems use a holographically recorded image of the test object itself as a master against which the test object is compared after exposure to, for example, an applied stress. Depending on the inspection technique used, the interferometric comparison of the test object with its reference image can be made continuously (real time) or at selected instants in time (multiple exposure). This latter technique takes advantage of the fact that more than one hologram can be made on the same recording medium. Periodic vibratory motion can be examined with time-average holographic interferometry, while high-speed displacements or deformations can be studied with pulse methods.

The following sections will provide brief and qualitative descriptions of the basic holographic interferometry methods. A discussion of the quantitative information that can be obtained with these methods is presented later.

Real-Time Interferometry

In the real-time technique of holographic interferometry, a CW laser is used to make a hologram of the object in its natural or undisturbed state or in some other useful reference state, and the holographic reconstruction is compared to the object itself as it is deformed in real time. With the hologram being used as an observation window, it is possible to observe the resulting interference pattern produced by the interaction of the recorded object beam (also referred to as the stored, or frozen, beam) with the modified, real-time object beam (sometimes referred to as the live beam). With this method, it is possible to observe interference fringes resulting from differential, stroboscopic, and time-averaged motion of the object surface. Stroboscopic visualization can be obtained by chopping the laser source at a frequency and phase linked to the object excitation source. For time-varying fringe fields, time averaging is performed by the observer's eye, permitting the identification of nodes and antinodes of displacement when the object is excited at some vibratory resonance.

Multiple-Exposure Interferometry

The double-exposure, or differential, technique of holographic interferometry involves the use of either a continuous-wave or a pulsed laser to record two holograms—one of the object in its natural or undisturbed state (or in some other useful reference state) and the other of the object in some changed or disturbed state. Both holographic recordings are made on the same piece of film so that in the reconstruction process, the two recorded object beams interfere with each other to produce a fringe field in which the contour and spacing describe the changes that occurred between the two exposures. Because both the master and the test images are holographically recorded, high-speed disturbances such as stress wave propagation or ballistic impact can be examined using the double-exposure technique and double-pulsed laser

sources. Laser pulse durations of several nanoseconds can be used to freeze surface motion that cannot be readily observed in real time.

One important variation of the double-exposure recording process incorporates two angularly separated reference beams. One of the beams is used for each exposure. When the resulting hologram is reconstructed by either beam alone, the image in the primary diffraction order contains no interference fringes, because only a single corresponding object beam is reconstructed. With both reference beams illuminating the hologram, the reconstructed image appears as one that might be obtained from a conventional double-exposure hologram with a single reference beam. The advantage of the dual-reference double-exposure technique derives from the ability to independently access the two reconstructed images to be interfered. By changing the frequency or phase of one reconstructing beam relative to the other, the observed fringes can be made to move in such a manner as to facilitate the quantitative interpretation of the interferometric information with measurement accuracies approaching 1/1000 of a fringe.

The stroboscopic technique of holographic interferometry involves the multiple recording of certain predetermined positions of an object in periodic motion, usually at the vibrational antinodes, the positive and negative maximum amplitudes of vibration. A pulsed laser or a continuously chopped CW laser synchronized with the source of vibrational excitation is ordinarily used to make these recordings. In the reconstruction process, fringes of high contrast are produced that enable the measurement of large amplitudes of vibration. By appropriately timing the laser pulses during holographic recording, the phase relationships of the antinodes can also be obtained.

Time-Average Interferometry

The continuous-exposure technique (time-average technique) of holographic interferometry permits mapping of the displacements of the surface of an object in periodic motion. A CW laser is ordinarily used to make this recording. Because the holographic exposure time is usually much greater than the period of object motion, the hologram is a record of the time-averaged irradiance distribution at the hologram plane. In the fringe field resulting upon reconstruction, bright fringes correspond to nodal regions (regions of zero or very small amplitudes of vibration). Fringe order increases as one approaches antinodal regions (regions of large amplitudes of vibration). By using appropriate fringe analysis techniques, the amplitudes of vibration for each point on the surface of the object can be determined. Because the fringe contrast decreases as the amplitude of motion increases, the displacement amplitudes analyzed in this way should not be too great.

Holographic Contouring

In addition to being a powerful tool for studying the response of an object of complex shape to a variety of applied stresses, holographic interferometry also provides a convenient means of evaluating the shape itself. With the appropriate techniques, it is possible to produce interferometric fringes that are a function of surface contour rather than surface deformation or displacement. Principally, two double-exposure recording methods are employed for this purpose: dual wavelength and dual refractive index methods.

The dual wavelength method for holographic contouring requires that the two holographic exposures be made at slightly different laser wavelengths. A CW gas laser such as an argon ion laser is usually used for recording purposes because the laser cavity can be easily tuned to any of several operating wavelengths. Upon reconstruction of the hologram with one or the other of the two recording wavelengths, a fringe pattern, directly related to the surface relief of the object, is observed superimposed on the image.

The dual refractive index method requires that the object to be contoured be viewed through a flat window in a test cell or chamber containing the object. Between the holographic double exposures, the refractive index of the medium surrounding the object in the chamber is changed. The contour fringe rate is determined by the change in refractive index. When a high fringe rate is desired, liquids such as mixtures of water and alcohol can be used. For lower contour intervals, the pressure of air within the test chamber can be regulated to control the refractive index.

Optical Holography

Methods of Stressing for Interferometry

The nondestructive inspection of materials or structures by optical holography is potentially applicable to any problem in which stressing the part will produce a change in its shape that is indicative of the property or flaw being sought. Because holographic interferometry is most sensitive to displacements out of the plane of the specimen surface, stressing methods must be sought that will cause changes in the out-of-plane direction, which are detected by the recording of a holographic interferogram. The interferogram will consist of uniformly spaced dark and light bands (fringes), with a flaw being characterized as a distinguishable anomaly, such as a circular set of closed fringes. The part can be subjected to any of several types of stress, including acoustic, thermal, pressure (or vacuum), and mechanical. The type of stress used depends on:

- The physical characteristics of the part
- The type of flaw under inspection
- The accessibility of the part (whether the part can be tested by itself or must be tested as an integral part of a more complex system)

Acoustic Stressing. By combining optical holography with acoustic-stressing techniques, it is possible to record interferometrically the physical properties of relatively large surfaces as they are deformed by acoustic wave propagation and therefore to detect flaws. The acoustic stressing is done at sonic and moderately ultrasonic frequencies (usually less than 100 kHz). Excitation at frequencies in this range can be an important advantage of this approach over conventional ultrasonic inspection at megahertz frequencies because the effects of grain scattering, sonic attenuation, surface roughness, and shape complexity are all considerably minimized (see the article "Ultrasonic Inspection" in this Volume). This increases detection probability, permits the inspection of much larger areas at one time, and generally eases the transducer-coupling problem.

Application of acoustic-stressing systems for inspection is readily accomplished by electrically driving a piezoelectric transducer that has been bonded to the surface of the test object or to a fixture in which the object can be solidly mounted. The transducer vibrations are transmitted through the bond and cause flexural displacements of the component. In this way, with a proper choice of the driving frequency, a resonant-plate mode can be established in the test object. Additional transducers can be used as sensors to aid in establishing plate resonances. This technique of excitation has the advantage of producing a relatively broad range of frequencies--from a few hundred hertz to several hundred kilohertz.

In situations where larger-amplitude vibrations are required, a transducer can be mechanically coupled to a single point on the test object through a solid exponential horn (acoustic transformer). The horn consists of a cylinder whose radius decreases exponentially from one end to the other, with a piezoelectric transducer mounted on the larger end. The smaller end is pressed against the test object, and the transducer is driven at resonance to couple a large amount of acoustic energy into the test object. A typical setup is shown in Fig. 2. Such drive systems are generally limited to operation within narrow bands of frequency that are centered about the design frequency and its resonances. With this type of drive at 50 kHz, a peak displacement of about 10 μm (400 $\mu\text{in.}$) is obtained at the horn output. Horn-coupling excitation eliminates the bonding process required in the simple piezoelectric technique described above and is the most practical technique of acoustic stressing at high frequencies. This single-point method of excitation also permits the establishment of resonance throughout the entire test object, thus permitting inspection of the full surface at one time.

Fig. 2 Typical setup for the acoustic stressing of a test object using a piezoelectrically driven exponential horn

Standing, traveling, and surface waves can be utilized for inspection. Each is discussed below.

Standing Acoustic Waves. With standing waves, surfaces over debonds and voids, for example, can readily be made to vibrate, thus producing an easily distinguishable change in the mode pattern. Figure 3 shows two examples of areas of debonds detected with standing acoustic waves. Resonances within the skin covering the debonded area may require the application of increasingly higher frequencies as the size of the debonded region to be detected becomes smaller. Broadband acoustic excitation over a band of frequencies is often used to excite motion in debonded regions that may vary in size.

Fig. 3 Optical holographic interferograms showing areas of debonds (arrows) that were detected with standing acoustic waves. (a) Debonds between a compressor fan blade and a metal strip protecting the leading edge. (b) Debonds between the metal face sheet and the honeycomb-cellular core of a sandwich structure

component is one of the simplest methods.

Electrical-resistance heating tape applied to a specific area of the test object is a method for preferential thermal stressing, as is a heat gun.

Resistance heating of the object itself can be performed by passing electrical current through it.

Hot-air heating or liquid-nitrogen cooling can also be utilized as a thermal stressing method. For hollow or channeled components, the heated or cooled gases can be passed through the test object where accessible.

In addition to steady-state and transient heating methods, periodic heating of the object and synchronized strobing of the real-time holographic imaging system have been effective in locating surface-breaking cracks and similar defects.

Pressure or Vacuum Stressing. One of the most effective methods of stressing hollow components for holographic inspection is pressurization or evacuation. This method is most easily implemented in situations where access is available to the internal cavity. However, it is not limited to this type of test object. For any sealed-off structure that is manufactured at atmospheric pressure, external evacuation can be utilized to create a pressure differential between the

Traveling Acoustic Waves. With traveling waves, acoustic energy will be scattered or absorbed at locations where the test object has a flaw. This scattered energy can be observed as an anomaly in the surface displacement in a holographic reconstruction of the test object. It is important to note, however, that the dynamic characteristic of traveling waves requires pulsed-laser holographic procedures, while standing waves are amenable to both CW laser and pulsed-laser holography.

Surface waves (Rayleigh waves) offer another acoustic approach, but require some sophistication in their generation to achieve sufficient amplitude for easy holographic observation. They are, however, easily attenuated by changes in structure and therefore offer potential for the detection of such flaws as surface microcracks in metal components. Electromagnetic drive systems can also be used to excite the test object and are generally quite easy to effect. For inspecting nonferromagnetic materials, some preliminary preparation, such as coating with magnetic paint, is required.

Thermal Stressing. The use of thermal stressing for successful holographic nondestructive inspection relies on changes in the surface deformation caused by differences in thermal expansion that are a direct result of a flaw or feature of interest. For example, when there is a lack of intimate contact at a debond between two components made of materials with different thermal conductivities, the lower rate of heat removal from the debonded region can affect the surface expansion in such a way as to create an anomaly in the interferometric fringe pattern of the hologram. In general, thermal stressing causes time-varying changes in surface displacement and therefore is best used in conjunction with real-time CW laser or pulsed-laser holographic techniques.

Many methods are available for applying a thermal stress to a component under test. The method used and its applicability depend on the particular application.

Radiant Heat Sources. Radiation from a heat lamp or a photoflood lamp directed onto the front or back surface of the

cavity and the environment. An example of this latter approach is presented in Fig. 4, which shows an area of debond between the core and an aluminum faceplate of a honeycomb-core sandwich panel.

Fig. 4 Optical holographic interferogram of a pressure-stressed honeycomb-core sandwich panel. The sandwich panel was stressed by the atmospheric pressure of the air sealed in the core cavities when the air surrounding the panel was evacuated. An area of debond between the core and the near faceplate (of aluminum) is indicated by the fringe pattern in the vicinity of the ink marks on the faceplate. The background fringes were caused by general movement of the faceplate during evacuation.

In general, very mild pressure stressing (0 to 70 kPa, or 0 to 10 psi) is sufficient to produce a surface change capable of detection by the holographic interferometric technique. However, in some cases (for example, the inspection of diffusion bonds and electron beam and resistance welds), large pressure differentials of the order of 700 kPa (100 psi) are required to create enough surface deformation for holographic interferometric detection. In these cases, the possibility of inspection by pressure stressing of hollow components when internal access is not available is precluded because external evacuation would not provide a sufficient pressure differential.

Mechanical Stressing. Another method for deforming a test object during holographic interferometric inspection consists of subjecting it to simple mechanical force. There are numerous ways of applying mechanical force, but the technique chosen will depend on the shape of the test object and the type of flaw being sought. One method that has found relatively wide acceptance for the vibration analysis of components is the use of mechanical shakers.

Optical Holography

Inspection Procedures

As previously mentioned in the section "Holographic Recording" in this article, optical holography utilizes both continuous-wave lasers and pulsed lasers.

Continuous-Wave Techniques

Generally, in developing a procedure for the holographic inspection of a specific component or class of components, the common CW technique of laser holography is initially used to:

- Study engineering aspects of the problem
- Evaluate various stressing methods
- Develop an effective test procedure

Subsequently, specialized adaptations of the CW technique can be designed to eliminate or minimize the potentially deleterious effects of environmental vibration and the associated need for massive vibration-isolated tables. Indeed, for the inspection or testing of manufactured parts from an assembly line, it may be necessary to provide sufficient vibration isolation from the factory environment. In such situations, with adequate vibration isolation, the straightforward, widely used and well-developed conventional holographic procedures can be implemented.

However, in many cases, inspection cannot be done with a CW technique. This is especially true when:

- The most effective stressing procedures involve noncyclic dynamic loading
- The inspection must be performed without using a stable (holographic) table
- The inspection area cannot be darkened to facilitate recording of the hologram
- Specialized test facilities must be used

In such situations, holography using a pulsed-laser beam offers one practical approach to nondestructive inspection.

Pulsed-Laser Techniques

Continuous-wave lasers are used in optical holography at widely varying power levels and wavelengths. However, when high-speed transient stressing is used or when the test environment is unstable or hostile, a pulsed-laser technique has been most successful for making holograms. The most common pulsed lasers used for holographic applications are flash lamp pumped solid-state lasers such as ruby and frequency-doubled neodymium-doped yttrium aluminum garnet (Nd:YAG).

The process of making holographic interferograms with a pulsed laser can be more complicated than it is with CW lasers. Because laser pulse duration determines the exposure times, which may be of the order of several nanoseconds, precise synchronization of the laser with the excitation source is usually required. An additional complication arises if a stable environment is not used for the pulsed system. In this case, if a single exposure of a specimen is made, followed a few seconds later by a second exposure of the same object without applying any excitation, the resulting hologram will be found to be covered with a number of uninterpretable fringes caused by atmospheric changes and rigid-body specimen displacements that occurred between exposures. If this procedure is used to record an interferogram in the same manner as with the CW technique, the fringes resulting from the presence of a flaw may not even be visible. One solution to this problem is to pulse the second exposure a sufficiently short time after the first so that no significant rigid-body motion can occur between exposures. Elaborate switching systems have been created to perform this function. A typical pulse sequence might be a first exposure of 20 ns, a delay of 25 μ s, and then a second exposure of 20 ns.

With pulsed-laser techniques, the nature of the excitation required for the detection of flaws can be quite different from that used with CW techniques. One method is to impact the test object and thus trigger the pulse sequence. Fringes tend to form around or in the vicinity of flaws because of a difference in the mechanical properties and therefore in the response of the surface. These effects are entirely too brief to record by CW techniques. The same type of effects will be recorded by pulsed-laser techniques if the component is thermally excited before the pulse sequence in such a way that the specimen is still deforming thermally during exposure.

Because the requirement of environmental stability is greatly reduced when pulsed-laser techniques are used, the laser and the necessary ancillary optical components can be installed in an existing testing facility to perform holographic interferometry. The laser head and its power supply can be placed in any convenient, nearby location. A beam splitter and several mirrors are used to generate two approximately equal optical beam paths to illuminate the test object and to provide a reference beam, and the photographic plate is clamped in position to view the test area of interest. A portable pulsed-laser setup is shown in Fig. 5.

Fig. 5 Schematic of a portable setup for producing a pulsed-laser holographic interferogram of an area on a sandwich-structure helicopter-rotor blade being subjected to fatigue stressing

Pulsed-laser systems can be subdivided on the basis of the operational mode used to generate the holographic interferogram, that is, Q-switched and conventional pulse mode. The conventional pulsing of a flash lamp pumped solid-state laser occurs simultaneously with the excitation of the flash lamps, so that the laser output may last for up to 2 ms. By placing a Q-switching element in the laser cavity, short pulses (tens of nanoseconds) can be produced during a single flash lamp cycle.

Q-Switched Pulse Mode. Double exposures using two Q-switched pulses from separate flash lamp cycles, perhaps operationally the easiest to effect, permit the recording of an essentially static test object in two different stress states. The distinction between this and the conventional CW holographic interferometric procedure lies in the extremely short duration of each individual exposure, which can often obviate the need for sophisticated vibration-isolation tables. Some stability must be retained, however, because gross movement of the object would simply result in the formation upon reconstruction of two images (similar to a double-exposed photograph) without the characteristic fringe pattern associated with holographic interferometric inspection. In practice, holographic exposure of the test object is recorded, a stressing force is applied, and a second exposure is recorded, with the time interval between exposures (several seconds to many minutes) being dependent on the mechanics of the test.

Double pulsing of the Q-switch during a single flash lamp cycle is more widely used and perhaps the best known pulsed holographic interferometry technique. The method uses a double Q-switching action to generate both output pulses during a single optical pumping cycle of the laser. As such, the exposure-time interval is variable from microseconds to 1 or 2 ms; the lower limit is a function of the laser characteristics and Q-switching electronics, and the upper limit is controlled more by the characteristics of the flash lamps used to optically pump the laser. Consequently, this mode of operation greatly reduces restrictions placed on the holographic process by virtue of the physical environment and is directly applicable to many dynamic events. Generating two matching pulses, however, becomes more difficult as the pulse-separation time exceeds 200 μ s because of the dynamic thermal conditions in the laser cavity. The result is images with contour fringes that modulate displacement fringes, thus obscuring the information sought. In addition, the stressing force appropriate to manifesting the flaw of interest must be capable of rapid application--a feature that may limit the effectiveness of the method in some instances.

Conventional Pulse Mode. In a conventional pulse (non-Q-switched) mode, a long-duration (1 to 2 ms) pulse is used for recording interferograms. This approach offers several advantages. First, the pulse duration is short enough to isolate objects that are moving because of environmental vibrations with frequencies of 100 Hz and less, while still permitting time-average studies of intentionally induced vibratory excitation of a component at frequencies of 1000 Hz and higher. Second, the total energy in the laser pulse is increased by a factor of ten over a Q-switched pulse for the same flash lamp

power, permitting larger surface coverage. The most important aspect of these features is the vibration-analysis capability, for it permits application of the pulsed technique in those situations where cyclic acoustic excitation is the preferred method of stressing the testpiece.

Optical Holography

Revised by James W. Wagner, The Johns Hopkins University

Effects of Test Variables

In performing nondestructive inspection by optical holographic techniques, several important test variables should be considered. Some variables, such as exposure time and reference-to-object-beam intensity ratios, are controllable by the operator, while others are not (for example, the physical test environment). Although there are considerable interrelationships among test variables, for the purposes of this discussion they have been divided into the following eight categories:

- Object size
- Exposure parameters
- Surface finish
- Surface preparation
- Surface condition
- Whole-body motion
- Ambient illumination
- Environmental vibration

Object Size

There are of course theoretical limits on the size of object that can be inspected by optical holography, but generally there are practical considerations that set the upper bounds.

Laser Coherence Length Limitations. The theoretical limitation is imposed by the finite coherence length of the laser determined by the natural broadening of the laser spectral line. Because the instantaneous frequency of the light leaving the laser cavity varies over some narrow range with time, light exiting the laser at one instant may not be coherent with that emitted at some other instant. Therefore, the coherence length is the distance that light leaving the laser can travel before there is a shift in instantaneous laser frequency sufficient to produce light that is no longer coherent with that which left the laser initially. As a result, to produce successful holographic recordings, the path length difference between the reference and object beams must not differ by more than that coherence length.

With essentially flat objects mounted parallel with, and close to, the holographic plate, it is necessary to consider the difference in path length between the point on the object closest to the film plate (essentially the normal between the two) and the point on the object farthest from the plate. Generally, if this difference exceeds the coherence length, thus prohibiting complete holographic coverage, it is possible to move the holographic plate farther away from the object, thus decreasing the length differential between these two points on the object. In addition, if the object itself also has considerable depth along a path normal to the holographic plate, conventional holographic procedures will limit the portion recorded to a distance equal to a maximum of one-half the coherence length of the laser, depending on recording geometry.

However, because lasers with coherence lengths of the order of several meters are readily available and because inspection by optical holography generally involves normal or near-normal observation of the surface of the object, other practical limitations will almost always prevail in establishing maximum object size and/or surface coverage.

Vibration-Isolation Table Capacity Limitations. When a CW laser is used, the object and holographic components must be rigidly mounted to a common fixture, which is itself isolated from the environment. This is generally accomplished with vibration-isolation tables, which in turn place a practical upper limit on the size of the object that can be recorded; commercial tables are available that are large enough to permit the holography of objects with several square

feet of surface area and weighing several hundred pounds. When using a pulsed laser, because vibration isolation is less important, the holographic plate can be placed at as great a distance from the object as is desired or is physically possible. In this situation, the practical limits of size are then set by the available energy output of the laser; commercial systems with outputs of up to 3 to 5 J/pulse (0.8 to 1.4 mWh/pulse) are currently available, permitting coverage of areas in excess of 9.3 m² (100 ft²) in a single hologram.

Exposure Parameters

When using a CW laser and proper vibration isolation and control over the ambient light, the exposure time is a function of the film sensitivity, the size of the object, and its reflective properties. A proper ratio must be maintained between the reference beam intensity and object beam intensity, which is most easily controlled with adjustable beam splitters. (Neutral-density filters, and polarizing filters if the laser has a polarized output, can also be used in the reference beam path for preferential control of the beam ratio.) It is generally desirable to use a reference-beam intensity somewhat higher than the object-beam intensity, giving a ratio as measured at the holographic plate perhaps as high as 2:1 for real-time, 3:1 for double-exposure, and 4:1 for time-average techniques. (Measurement at the holographic plate automatically accounts for the reflective properties of the object.) However, the optimum exposure time and beam ratio for a particular component are best determined by trial and error; exposure times of seconds to minutes are not uncommon, and beam ratios as high as 10:1 or 20:1 are sometimes used. The important consideration in judging the results of varying the exposure time and the beam ratio is the fringe contrast in the reconstructed image, with the goal being high-contrast fringes.

When using a pulsed laser, the exposure time is fixed by the laser characteristics. Although some control of exposure time can be exercised when operating in the conventional pulse mode (1 to 2 ms) by controlling the laser pumping variables such as voltage and capacitor storage, the more commonly used Q-switch systems have fixed exposure times in the 10 to 50 ns region.

Surface Finish

Investigations of surface finish have demonstrated that it imposes no severe limitations on the holographic process as applied to the nondestructive inspection of metal parts (Ref 1). Surfaces varying from 0.1 μm (4 μin.) (very highly polished) to 25 μm (1000 μin.) root mean square roughness (quite rough) are easily recorded with no significant effect on interferometric fringe location. However, optimum contrast is not always obtained, particularly with polished surfaces, which can act as specular reflectors.

Specular reflection of the light source onto the hologram reduces image visibility and causes image smearing. In addition, specular reflections from low-roughness metal surfaces are brightest in a direction that is both a specular direction and a direction perpendicular to the finishing direction. Either specular directions or finishing directions may limit the area that can be recorded.

Surface Preparation

Because surface roughness imposes no severe limitations on holographic inspection, no preparation of the object surface is required; this is one of the most important advantages of this type of inspection. However, where permissible, surface preparation can be used to facilitate the inspection process by:

- Allowing greater area coverage and therefore reduced inspection time
- Eliminating the bothersome specular effect noted above and therefore simplifying data readout
- Producing a more uniformly bright reconstruction, which improves the overall fringe contrast and eases interpretation of the reconstructed image
- Permitting greater reflectivity from nonmetallic materials such as polymers and composites

To increase the intensity of the reflected light (increasing the area coverage and often improving the fringe contrast) or simply to minimize specular effects, any reasonably diffuse, flat, water-base white paint is generally satisfactory and easy to remove. Still greater increases in reflected light intensity (permitting even larger area coverage or reduced exposure time when using a CW laser) can be achieved with metallic paints or reflective paint of the type often used on highway

signs. Regardless of the paint used, it must be allowed to dry completely. If the paint structure changes between exposures, no fringes will be produced.

Surface Condition

Because optical holographic inspection compares the surface of the test object in two states of stress, it is important that the condition of the surface remain as constant as possible between exposures. Dust, dirt, grease, oil, corrosion, wear, pitting, and loss of paint might be erroneously identified as displacement caused by a flaw if proper care is not exercised during the inspection procedure.

Whole-Body Motion

Quite often, the stressing force applied to manifest a flaw as a change in the surface shape also causes a general overall movement of the object under test. This movement is sometimes referred to as rigid-body or whole-body motion. The movement may or may not prevent proper interpretation of the reconstructed holographic interferogram, but it can be disconcerting. In certain situations (when performing real-time CW holography), fringe-control techniques can be used to compensate for rigid-body motion.

Fringe-Control Mirror. One approach to fringe control requires the incorporation of an additional mirror, having two axes of rotation, as the last element in the optical train of the object-illumination beam. If the object now rotates slightly during application of the stressing force, a linear phase change will be introduced into the optical beam reflected to the real-time hologram. The optical interference between this beam and the holographically reconstructed beam will introduce a fringe pattern along the object when it is viewed through the real-time hologram. By tilting the object beam in an appropriate manner, using the additional fringe-control mirror placed into the system, adequate compensation for the phase change introduced by the object rotation can often be accomplished. Therefore, most of the unwanted fringes can be eliminated, and the anomalous fringe pattern around a flaw can be better revealed (Fig. 6).

Fig. 6 Optical holographic interferograms of a clamped sandwich panel, illustrating use of fringe-control technique to eliminate unwanted fringes. (a) Interferogram showing unwanted fringes caused by stresses from a clamp (at top center). (b) Interferogram of the same clamped panel as in (a), but recorded with the use of a fringe-control mirror to eliminate the clamping-stress fringes, thus revealing a fringe pattern (at bottom center)

caused by a flaw

The appropriate setting of the fringe-control mirror can best be determined by slightly rotating the mirror about each axis of rotation while simultaneously viewing the object through the hologram. By noting the direction of rotation that tends to broaden and separate the fringes, the appropriate rotational direction can be found. In practice, several such adjustments about each axis are usually required to produce the broadest spacing of fringes on the object.

Phase-Change Compensating Lens. Another method of fringe control incorporates a lens, which can be translated along its optical axis, in the object beam path to compensate for undesirable phase changes caused by object movement (Ref 2). Furthermore, this method can be adapted to double-exposure techniques by using a different reference beam for each exposure and both reference beams in the reconstruction step.

Ambient Illumination

Holography is most easily performed in a darkened area. In the presence of any ambient illumination that cannot be controlled, pulsed-laser techniques are usually the most desirable. With such techniques, the holographic plate can be shuttered in synchronization with the laser pulse (or pulses, if used in the double-pulse mode) to hold fogging of the film to an acceptable level.

Focal-Plane Shutters. Specially modified focal-plane shutters to provide a full opening for a few milliseconds are quite satisfactory. This opening duration is long enough to encompass both pulses when used in the double-pulse mode and is short enough to permit holography in almost any factory environment. Successful tests have been performed with as high as 2.2 klx (200 ftc) of reflected ambient light, as measured at the film plane, using shutter durations of the order of 75 ms (Ref 1).

Interference Filters. If necessary, the level of ambient radiation reaching the film can be further reduced by using optical filters matching the spectral content of the laser. Generally, a fairly broadband red filter is more than sufficient for ruby lasers. Highly tuned interference filters, which are available to match all common laser sources, can be used to essentially eliminate any ambient light problem. However, care must be exercised in the application of these filters because their transmission characteristics are highly dependent on incidence angle, thus greatly restricting the permissible optical configuration. Also, they are expensive, especially in larger sizes. However, they are useful for very specific configurations and applications, especially in the holography of self-luminous objects.

Air Turbulence and Environmental Vibration

The holographic recording process is extremely sensitive to variations in optical path length that may occur during film exposure. Unwanted variations in optical paths may be caused by turbulence in the air path through which beams are propagating or by sources of rumble and vibration in the environment.

Air turbulence problems are most severe when relatively long holographic exposures are called for and can be dealt with directly by shielding the holographic apparatus or enclosing the beam paths in a series of interconnecting tubes. These effects can also be minimized by using optical fibers to deliver the light beams prior to beam expansion. Electronic feedback is sometimes used to control the position of a mirror to compensate for fluctuations in refractive index caused by air turbulence.

Environmental Vibration Problems. In most cases, air turbulence effects are less troublesome than the effects of environmental vibration. Pulsed-laser systems have been effectively used for practical testing outside of a vibration-controlled optical laboratory. Pulsed lasers are extremely effective in these situations and therefore allow the use of nondestructive inspection by optical holography in most factory environments. By maintaining the pulse-separation interval during the recording of a double-exposure holographic interferogram at or below a few hundred microseconds, any environmental vibration effects below 1000 Hz are obviated. Although the higher-frequency vibration of objects would hamper successful testing, such vibrations are generally of sufficiently low amplitude in normal industrial environments to be of no consequence.

If the use of pulsed-laser systems is undesirable or if the nature of the test (such as low-frequency vibration analysis) necessitates CW techniques, various methods are available for vibration compensation. These techniques include:

- Speckle reference beam holography (Ref 3)
- Focused-image holography (Ref 4)
- Optical processing of the reference beam (Ref 5)
- Attachment of the reference beam mirror (Ref 6) or the photographic plate itself to the object (Ref 7)

All of these techniques can generally be classed as local reference beam generation methods, in which the motion of the object is automatically compensated for by a comparable change in the reference-beam path.

Electronic-feedback servosystem methods to provide reference beam compensation by both phase modulation (Ref 8) and frequency modulation (Ref 9) are also available. Finally, the use of scanned-beam holography offers an approach to compensation for object movement (Ref 10). In general, these methods require a reasonably good working knowledge of holography because of their more complex nature and would be further troubled by any existing ambient illumination. These object motion compensation methods, as well as fringe-control techniques, are discussed in Ref 11.

Optical Holography

Revised by James W. Wagner, The Johns Hopkins University

Readout Methods

When using a reconstructed interferometric image for holographic inspection, something more than a simple visual display is generally required. A permanent record of the image, such as a photograph, is most commonly used. If further data reduction is to be done on the interferogram, some form of electronic image is more convenient than a photographic image. Photographic and electronic methods of readout of holographic interferograms are discussed below.

Photographic Readout

Photographic readout with a small-format camera, such as a 35 mm single lens reflex camera, is adequate for many inspection tasks. A reflex-type camera is recommended because the picture can be composed. A wide variety of film is available for 35 mm cameras. The film can be obtained economically in bulk form and loaded into cartridges as needed. Slightly more expensive, but more convenient, are preloaded cartridges of 20 or 36 exposures.

Interchangeable Lenses. It is convenient, but not essential, for the camera to have interchangeable lenses. Most needs can be met with a standard 55 mm lens--the faster the better. For photographing remote images, a telephoto lens (for example, one with a 135 mm focal length) is often desirable. Extension tubes 25 and 50 mm lengths are an inexpensive but useful way to obtain closer working distances from the standard 55 mm lens. Several wide-angle to medium-telephoto macrozoom lenses are available. Generally, in making holographic reconstructions, the light levels are fairly low, so lenses with small f -numbers are recommended for shorter exposures and smaller speckle size.

The better the quality of the photographic negative, the better the final print. For the best negatives possible, a large-format camera, such as a 100 by 125 mm (4 by 5 in.) view camera, should be used. Such a camera also provides the option of using Polaroid film, which is often quite convenient. A standard 135 mm lens will serve for most purposes. A 90 mm wide-angle lens and a 250 mm telephoto lens will accommodate unusual situations.

Photographic Film Specifications. The choice of photographic film is not critical. Some inadequacies in the original reconstruction can be partially compensated for in the darkroom. For example, the recording of high-contrast, high-order fringes in a time-average interferogram requires a dynamic range not obtainable with existing film material. To compensate for the overbright, zero-order fringe and to enhance the weaker, higher-order fringes, a superproportional reducer such as a 20% solution of ammonium persulfate can be used. The reducer takes silver from those portions of the negative where there is the most, thus enhancing the weakly recorded higher-order fringes. Special high-contrast copy films, such as Kodak 410, are available and are excellent for making reconstructions that are to be used for quantitative data reduction. For maximum resolution in the reconstruction, moderate-speed or slow-speed films are best. In general, the faster the film, the grainier the image. When a high f -number camera is used, however, graininess of the image will be determined by speckle size, not film noise. For qualitative purposes or for a record only, almost any film can be used. For convenience, high-speed films, such as Polaroid type 57 (ASA 3000), are favored.

It is not possible to record everything that can be observed in the holographic image. Lateral motion often prevents a fringe pattern from localizing on the surface of the object. As a consequence, when a large-aperture optical system having a very short depth of field is focused on the object, the fringes may vanish. They lie outside the depth of field of the lens and are blurred out. To increase the depth of field, the lens aperture can be decreased, but this also increases the size of the speckles in the resulting reconstruction.

Electronic Readout

Photographs serve well for archival purposes. However, if there is to be any further manipulation of the data, position and density information in the photographic negative or in the image must be converted to numerical values. This can be accomplished by using a standard television-type video system and one of several flexible, multiple-purpose systems for electronic image processing. Analog image processors permit several types of image enhancement, including edge enhancement, boundary detection, area determination, particle counts, and color coding of displays by density level.

The digital image processing of holographic images permits direct and automatic interpretation of fringe patterns, resulting in psuedo-three-dimensional displays of object contour or deformation. Computer algorithms are available for the conversion of fringes from a single interferogram image. In addition, the holographic recording and readout system can be altered so that several images of the interferogram can be processed to produce displacement information, providing in some cases nearly a 1000-fold improvement in sensitivity over conventional holographic interferometry. Among these techniques are phase stepping and heterodyne holographic interferometry. The principles behind their operation are explained in the section "Interpretation of Inspection Results" in this article.

For inspection functions, many of the standard video methods are applicable. Because the diffraction of a typical hologram is low (<3% of the incident light), it is advisable to use a television-type video system with a camera capable of operating at low light levels, although a standard television camera is often satisfactory. Cameras capable of operating at low light levels are discussed in the section "Television Cameras" of the article "Radiographic Inspection" in this Volume.

The resolution available with electronic readout varies from that afforded by charge coupled device array cameras and standard 525-line video cameras to 1000- and 2000-line high-resolution video cameras. For even higher resolution, a special scanner-type readout system, such as an image dissector, flying spot, or laser scanner, is required. However, because these special scanning systems generally work from photographic film inputs, their high resolution is gained at the expense of not being able to take advantage of the real-time nature of electronic readout.

Data Storage and Retrieval. When using electronic readout, videotapes can be made for archival purposes. For rapid response and more accurate timing, video storage disks and scan converters can be used. In building a library of patterns, any of the electronic storage media mentioned above can be used to advantage in conjunction with photography. For example, a video system can be used to isolate and temporarily store a pattern of interest, which can then be photographed from the monitor for permanent or individual storage. Photographs are much less expensive than any form of electronic storage.

Optical Holography

Revised by James W. Wagner, The Johns Hopkins University

Interpretation of Inspection Results

The holographic process can be considered merely an optical high-fidelity recording process; the reconstructed image of an object is indiscernible from the object seen with the unaided eye. Whatever the source, the observer sees an intensity distribution of light that produces, using the optical system of the eye, an image of the object.

When a holographic interferogram is viewed, a system of fringes is seen overlaid on the object (Fig. 7). Different object motions produce different fringe patterns. In general, the more complex the object motion, the more complex the fringe pattern. The fringe pattern in a holographic interferogram of a diffusely reflecting object can be used to extract quantitative information about the object. The procedures for interpreting the patterns depend on the type of hologram and are presented for the most common cases later in this section.

Fig. 7 Schematic of the reconstruction process of a virtual image of an object showing fringes from a double-exposure holographic interferogram

It is important to remember that optical holographic interferometry measures directly only surface deformation or displacement. The information in the fringe pattern and the holographic image are directly related to the fine structure of the surface. Should the fine structure of the surface be altered between the "before" and "after" exposures in a double-exposure interferogram, which is the most common form of holographic interferogram, the loss of contrast in the resulting fringe pattern will reflect that change. The general change in the shape of the test object is portrayed by the fringe pattern itself. It is only this aspect of the interpretation of the fringes that is considered in the following discussion.

Qualitative Results

There are many cases in which quantitative results from fringe analysis are neither necessary nor desirable. For example, qualitative information is sufficient in the inspection of laminated or sandwich structures for debonded regions. It is of no

particular significance how much the debonded region has puckered. What is important is the extent of the debonded region and whether or not it is a debilitating flaw in the structure. The question of what size a debonded region must be in order to qualify as a debilitating flaw is outside the realm of holography. The inspector's experience and the intelligent use of the inspection device are what matter in this area of interpretation. The question of pattern recognition and what constitutes a pathological or bad specimen arises. Perhaps the safest way to proceed is to compile a library of anomalous fringe patterns from known bad or pathological specimens. Representative types of fringe anomalies include:

- Independent, localized fringe systems
- Abrupt changes in fringe continuity
- Abrupt changes in fringe density
- Significant changes in fringe shape

Depending on the amount of data or samples to be treated, the library of patterns can be further classified into types of anomalies as experience dictates.

Out-of-Plane Displacements Versus In-Plane Displacements. In general, out-of-plane displacements lead to fringe patterns that localize close to the surface of the object, while in-plane displacements lead to fringe patterns that do not localize on the object. If the object and the fringe pattern are to be recorded in the same photograph, they must both be within the depth of field of the lens of the recording camera. The concept of homologous rays is useful in understanding fringe localization (Ref 12).

The Characteristic Function

To understand what the fringes in a holographic interferogram represent, the concept of the characteristic function is useful (Ref 13). The distribution of the object intensity and the system of fringes observed in the interferogram can be considered to be the product of the square of the characteristic function, M , and the image intensity distribution, $I_0(x)$, that is:

$$\langle I(x) \rangle = M^2 I_0(x) \quad (\text{Eq 1})$$

Wherever the characteristic function goes to zero, fringes are seen on the object. In this case, M^2 might well be referred to as a fringe function. Only when the character of the object motion is well known can the characteristic function be determined. Once the characteristic function is known, quantitative information can be extracted from the interferogram. For step-function motion, such as that used to produce double-exposure interferograms, the characteristic function, M , is a cosine function of position and object displacement.

Out-of-Plane Displacements

If it is known that the object of a double-exposure interferogram was in some motionless state during an initial exposure and that it was in a different motionless state during the second exposure, then one is able directly to deduce the characteristic function. In this situation, the characteristic function is $\cos(\mathbf{K} \cdot \mathbf{d}/2)$, where \mathbf{K} represents the sensitivity vector and \mathbf{d} is the vector connecting the old position, P , of a point on the surface of the object with the new position, P' , as shown in Fig. 8. The sensitivity vector is defined as $\mathbf{k}_2 - \mathbf{k}_1$, where \mathbf{k}_2 and \mathbf{k}_1 are the propagation vectors of the light scattered from the point in the directions of unit vectors \mathbf{n}_2 (that is, toward the interferogram and observer) and \mathbf{n}_1 (which is on the line that emanates from the focal point of the object beam spatial filter and passes through the point on the surface of the object), respectively. Each value of \mathbf{k} can be determined from the formula $\mathbf{k} = (2\pi/\lambda)\mathbf{n}$, where λ is the wavelength of the object beam.

Fig. 8 Schematic of the observation of a double-exposure holographic interferogram showing the vectors and angles relating to out-of-plane displacement of a point on the surface of the object from position P to position P' . See text for explanation of the symbols.

Dark fringes result whenever $\cos(\mathbf{K} \cdot \mathbf{d}/2) = 0$; that is, whenever:

$$(\mathbf{K} \cdot \mathbf{d}/2) = \left[\frac{(2n - 1)}{2} \right] \pi, n = 1, 2, \dots \quad (\text{Eq 2})$$

Writing in scalar form and solving for the component of \mathbf{d} parallel to \mathbf{K} , the following expression for out-of-plane displacements is obtained:

$$|\mathbf{d}| \cos \alpha = \left[\frac{(2n - 1)}{2} \right] \left[\frac{\lambda}{2 \sin \theta} \right] \quad (\text{Eq 3})$$

That is, each fringe except the first one represents a displacement of $\lambda/(2 \sin \theta)$ from the previous one. The first fringe represents only half that displacement. The relations among \mathbf{K} , \mathbf{k}_1 , \mathbf{k}_2 , \mathbf{d} , α , and θ are illustrated in Fig. 8.

The description given above is applicable in those cases when the fringes localize on the object and a definite order number, n , is assignable to each fringe. This holds in cases of out-of-plane displacement. This is the most sensitive way to apply holographic interferometry. Out-of-plane displacements from 15 down to 1.25 μm (600 to 50 $\mu\text{in.}$) can be measured in this way. By assuming continuity and choosing the best fit for the data, displacements can be measured with an accuracy of $\lambda/25$.

In-Plane Displacements

In-plane displacements can also be measured, but generally with lower precision than out-of-plane displacements. The fringe pattern for an in-plane displacement will exhibit parallax when viewed through the interferogram. As the observer's eye moves, the fringe pattern moves in either the same or the opposite direction with respect to a given point on the object surface. Each dark fringe that crosses a given point during eye movement corresponds to a value of zero for the characteristic function.

Scanning the interferogram from one side to the other, as shown in Fig. 9, defines a new vector, $\mathbf{A} = \mathbf{k}_2'' - \mathbf{k}_2'$. The displacement parallel to \mathbf{A} can be determined from the number of fringes that are observed to cross point P . Because zero values of the characteristic function occur at multiples of π , the expression for in-plane displacements that is equivalent to Eq 2 is:

$$(\mathbf{A} \cdot \mathbf{d}/2) = n\pi \quad (\text{Eq 4})$$

Writing in scalar form and solving for the component of \mathbf{d} parallel to \mathbf{A} , the following expression for in-plane displacements is obtained:

$$|\mathbf{d}| \cos \beta = \frac{(n\lambda)}{(2 \sin \phi)} \quad (\text{Eq 5})$$

That is, the component of \mathbf{d} lateral to the line of sight is proportional to the number of fringes crossing point P and is inversely proportional to the sine of the half-angle between the two views. The angle between \mathbf{A} and \mathbf{d} is called β .

Fig. 9 Schematic of the observation of a double-exposure holographic interferogram showing the vectors and angles relating to in-plane displacement of a point on the surface of the object from position P to position P' . See text for explanation of symbols.

It is possible to measure in-plane displacements from 5 up to 150 μm (200 $\mu\text{in.}$ to 0.006 in.) using double-exposure holographic interferometry (Ref 14). An error of $\pm 3 \mu\text{m}$ ($\pm 118 \mu\text{in.}$) can be expected on the large-displacement end of the range because of the limiting size of the interferogram (the limiting magnitude of \mathbf{A}).

For an object surface that undergoes a general displacement involving both in-plane and out-of-plane motion, the fringe pattern can be viewed from several (at least three) directions to obtain the projection of the surface displacement of each image point along at least three different sensitivity vectors, $\mathbf{k}_{1,2,3}$. The three sensitivity vectors can then be considered to be a set of nonorthogonal coordinate axes that can be rotated and projected onto a conventional coordinate system to obtain general object point displacements. Although the description of this process is a bit confusing, the mathematical and computer algorithms used to perform these manipulations are quite straightforward.

Time-Average Interferograms

The characteristic function for time-average holographic interferograms differs from that of the double-exposure case. If it is known that the object is undergoing strictly sinusoidal motion during the time of exposure of the holographic interferograms, then the characteristic function is $J_0(\mathbf{K} \cdot \mathbf{d})$, where J_0 is the zero-order Bessel function of the first kind and \mathbf{d} is the vector displacement. This function behaves similarly to a cosine function with regard to its zero values; however, it is not strictly periodic with zeroes existing at regular intervals. The first and second zeroes occur when the argument is 2.4048 and 5.5201. After that, the zero values can be approximated by those given by the asymptotic limit for large argument (large x); that is:

$$J_0(x) \rightarrow \sqrt{2/\pi x} \cos [x - (\pi/4)] \quad (\text{Eq 6})$$

For example, for the third fringe, the error is 15 parts in about 8600. None of the measurements to determine the values of θ or λ (Fig. 8) is likely to be this accurate, so use of the zero values for the asymptotic limit is generally well justified. Writing Eq 6 in scalar form and solving for the component of \mathbf{d} parallel to \mathbf{K} yields the following: For the first fringe:

$$|\mathbf{d}| \cos \alpha = 2.4048 \lambda / (4\pi \sin \theta) \quad (\text{Eq 7})$$

For the second fringe:

$$|\mathbf{d}| \cos \alpha = 5.5201 \lambda / (4\pi \sin \theta) \quad (\text{Eq 8})$$

For succeeding fringes, with $n \geq 3$:

$$|\mathbf{d}| \cos \alpha = (n - \frac{1}{4}) [\lambda / (4 \sin \theta)] \quad (\text{Eq 9})$$

To a good approximation, the first fringe represents a displacement of about $3\lambda / (16 \sin \theta)$, with succeeding fringes representing steps of $\lambda / (4 \sin \theta)$.

In addition to differences in the location of zeroes, the characteristic (Bessel) function for this case dramatically decreases in amplitude with increasing fringe order. Because of the decreasing brightness of the fringes and the limited dynamic range of the reconstruction film, it is difficult to record much more than seven fringes in photographically produced reconstructions. Even when a superproportional reducer is used on the reconstruction negative to increase the visibility of the higher-order fringes, it is difficult to work to much more than 30 fringes. In addition, it is difficult to work with a slope on the object in excess of about 0.6% with either double-exposure or time-average holograms, because of the high frequency of the fringes produced.

As mentioned previously, consideration has been given only to the relationship between holographic interference fringes and object surface motion. In fact, the appearance and apparent location of fringes in a reconstructed image depend not only on displacement but also on object surface reflectivity and fringe brightness or contrast. Therefore, the intensity at each point in a reconstructed holographic interferogram is a function of these three variables and not simply surface displacement. Using high-resolution methods such as phase stepping (Ref 15, 16) and heterodyning (Ref 17), one can compute directly all three variables at each point in the image to a degree of accuracy up to 1000 times better than can be achieved by simple fringe counting. In this way, displacements as small as 0.25 nm (2.5 Å) can be detected in principle.

To perform either of these interpretation methods, independent control of the two interfering images must be available during reconstruction. This is a natural consequence of real-time holographic interferometry because the reference and object beams can be altered independently. In double-exposure methods, however, a dual-reference arrangement as described previously must be used to permit independent control.

Phase-Stepping Methods. For phase stepping, several video images are recorded of the fringe pattern with a small phase difference introduced between the reconstructed images prior to recording each video image. The phase shift can be performed in several ways, but perhaps the most common method is to use a mirror mounted on an electromechanical translation device such as a piezoelectric element. If the phase shift imposed prior to each video recording is known, then only three images need be recorded. Because the intensity at each point on the image is known to be a function of the three variables described above, intensity information from the three images can be used to solve a series of three equations in three unknowns. In addition to providing automated interpretation of fringe patterns, phase stepping affords an increase in displacement sensitivity by as much as 100-fold ($\frac{1}{100}$ of a fringe) relative to fringe-counting methods. In practice, most investigators report a sensitivity boost of about 30.

Heterodyning Method. Still higher holographic sensitivity can be obtained with heterodyne holographic interferometry. As with phase stepping, independent control of the interfering images must be provided either by real-time analysis or dual-reference methods. Instead of introducing a phase shift between several recorded images, a fixed frequency shift is introduced in one reconstructing beam relative to the other. Typically, acousto-optic phase shifters are used to produce a net frequency shift of the order of 100 kHz. As a result, fringes once visible in the reconstructed interferogram are now blurred because of their apparent translation across the image field at a 100 kHz rate. A single-point optical detector placed in the image plane can detect this fringe motion and will produce a sinusoidal output signal as fringes pass by the detection spot. By comparing the phase of this sinusoidal signal to that obtained from some other point on the image, the difference in displacement or contour can be electronically measured. An entire displacement map can be obtained by scanning the optical detector over the entire image. Because scanning is required, the speed of heterodyne holographic interferometry is relatively slow. Sensitivities approaching $\frac{1}{1000}$ of a fringe have been obtained, however.

Optical Holography

Revised by James W. Wagner, The Johns Hopkins University

Holographic Components

The basic components of a holocamera are the:

- Light source (laser)
- Exposure controls
- Beam splitter
- Beam expanders (spatial filters)
- Mirrors
- Photographic plate or film holder
- Lenses
- Mounts for the equipment
- Tables to support the holographic system

Components and complete holographic systems are commercially available (Ref 18, 19).

Laser Sources

The characteristics of six types of lasers commonly used for holography are listed in Table 1. Helium-neon, argon, and ruby lasers are the most common. Helium-cadmium and krypton lasers, although not used as frequently, can fulfill special requirements for CW applications. Frequency-doubled Nd:YAG lasers are finding increasing popularity for pulsed holographic applications.

Table 1 Wavelengths and temporal coherence lengths of the six types of laser beams in common use for holography

Type of laser beam	Wavelengths			Temporal coherence length			
	nm	Å	Electromagnetic spectrum	Minimum		Typical	
				mm	in.	mm	in.
Helium-neon	633	6330	Orange-red	152	6	457	18
Helium-cadmium	422	4220	Deep blue	75	3	305	12
	325	3250	Ultraviolet	75	3	305	12
Argon	514	5140	Green	25	1	914	36^(a)
	488	4880	Blue	25	1	914	36^(a)
	(b)	(b)	(b)	25	1	914	36^(a)
Krypton	647	6470	Red	25	1	914	36
	(c)	(c)	(c)	25	1	914	36
Ruby	694	6940	Deep red	0.8	0.030	914	36

Nd:YAG	1064	10640	Infrared	(d)		(d)	
	532^(e)	5320^(e)	Green^(e)	(d)		(d)	

- (a) Typical temporal coherence length achieved when laser incorporates an etalon (selective filtering device) to make it suitable for holography.
- (b) Six other visible lines.
- (c) Nine other visible lines.
- (d) Varies with cavity design.
- (e) Frequency-doubling crystals

Helium-neon lasers are the most popular laser source when low powers are sufficient. Excitation of the gas is achieved through glow discharge. These lasers have excellent stability and service life with relatively low cost. Another type of laser is usually considered only when a helium-neon laser will not perform as required. A 20-mW helium-neon laser in a stable system can conveniently record holograms of objects 0.9 m (3 ft) in diameter. (Within the limits of coherence length and exposure time, as discussed previously, even larger objects could be recorded.) Such a laser consumes 125 W of 110-V electrical power and operates in excess of 5000 h without maintenance. A 5-mW laser records objects 460 mm (18 in.) in diameter and operates for more than 10,000 h without maintenance.

Helium-cadmium lasers are closely related to helium-neon lasers, with the following differences:

- Tube life is poor by comparison (approximately 1000 to 2000 h)
- The principal visible wavelength--422 nm (4220 Å) is 30% shorter (Table 1), which provides increased sensitivity and allows the use of recording mediums sensitive to blue light
- They have an output in the ultraviolet (325 nm, or 3250 Å), which is half the wavelength of helium-neon lasers and produces doubly sensitive displacement measurements
- There is more danger to the eyes at the shorter wavelengths produced by helium-cadmium lasers

Argon and krypton ion lasers can be the least expensive holographic sources on the basis of light output per dollar. Laser outputs of 1 W with 9 m (30 feet) of coherence length are available. Low-power argon lasers, however, are more expensive than helium-neon lasers. The use of an argon laser should be considered over a helium-neon laser in the following situations:

- When stability or dynamic conditions necessitate short exposures requiring high light power
- When the recording of large objects requires higher power to record good holograms
- When the recording medium requires high-power blue or green light
- When the holographic system needs the higher sensitivity provided by the shorter wavelengths of the argon laser

Argon lasers in the 1- to 4-W output range, equipped with an etalon (a selective filter required to achieve long coherence length), are excellent holographic light sources; however, a helium-neon or a helium-cadmium laser may be preferred for the following reasons:

- Argon lasers consume thousands of watts of electrical power and require water cooling
- Gas excitation is by electric arc, which generates high electrical and thermal loads on components and makes reliability and stability lower than with a helium-neon laser
- The output power is well above that which causes damage to the eyes, especially at the shorter wavelengths produced by argon lasers. Most available data indicate that helium-neon lasers are incapable of causing the damage that could be caused by an argon laser. Therefore, safety requirements for argon lasers must be more stringent

Krypton lasers are essentially the same as argon lasers except that the tubes are filled with krypton gas instead of argon gas. The output wavelengths are longer (Table 1) and the power is lower than for an argon laser. A 2-W argon laser produces 0.8 W in its most powerful line (514 nm, or 5140 Å), while the same laser device filled with krypton produces 0.5 W at 647 nm (6470 Å) and 1.3 W total. Argon and krypton gases can be combined in the tube to give custom outputs over a wide range of wavelengths.

Ruby lasers use rods of ruby instead of a gas-filled glass tube as a lasing medium. Excitation of the medium is by optical pumping using xenon flash lamps adjacent to the ruby rod. Ruby requires such high energy inputs to lase that the waste heat cannot be removed fast enough to sustain continuous output. For this reason, ruby lasers are always operated in a pulsed mode, and the output is usually measured in joules of energy per pulse (1 J of energy released per second is 1 W of power). Peak output powers of ruby lasers exceed 10 MW, requiring extensive safety precautions.

The development of pulsed ruby lasers for holography has progressed with the need to record holograms of moving (or highly unstable) objects. Ruby lasers have been extensively used to record the shock waves of aerospace models in wind tunnels, for example. Most holographic interferometry done with a ruby laser uses a double-pulse technique. The tasks that require a ruby laser are those that cannot be done with a helium-neon or an argon laser. Ruby lasers can routinely generate 1 J, 30-ns pulses of holographic-quality and relatively long coherence length light, which is sufficient for illuminating objects up to 1.5 m (5 ft) in diameter and 1.8 m (6 ft) deep.

The problem with ruby lasers lies in generating the two matching pulses required to record a suitable interferogram. Most lasers can be either pulsed once during each of two consecutive flash lamp cycles or Q-switch pulsed twice in the same flash lamp pulse to record differential-velocity interferograms. The pulse-separation time in the one flash lamp pulse mode extends to 1 ms. Generating two matching pulses becomes more difficult as the pulse-separation time exceeds 200 ms because of the dynamic thermal conditions in the laser cavity. The result is images with contour fringes that modulate displacement fringes, thus obscuring the information sought.

The operation of a ruby laser, when changing pulse-separation time or energy, requires the possible adjustment of flash lamp voltages, flash lamp timing with respect to the Q-switch timing, Q-switch voltages, and system temperatures. These conditions change as the laser system ages. Setting up the system requires many test firings to achieve stable performance. In short, operation of the laser requires high operator skill. In addition, the high performance of these systems requires care in keeping the optical components clean; buildup of dirt can burn the coatings on expensive optical components. The periodic replacement of flash lamps and other highly stressed electrical and optical components is to be expected. A helium-neon or a krypton laser is usually needed to reconstruct a ruby-recorded hologram for data retrieval. Differences between recording and reconstruction wavelengths lead to aberrations and changes in magnification in the reconstructed images.

Nd:YAG Lasers. Pulsed Nd:YAG lasers are constructed similarly to ruby lasers. Instead of a ruby rod, however, a neodymium-doped yttrium aluminum garnet rod is substituted as the lasing medium. The Nd:YAG laser is more efficient than the ruby system, but it operates in the near infrared at a wavelength of 1.064 μm (41.89 $\mu\text{in.}$). Frequency-doubling crystals with efficiencies of approximately 50% are used to produce light at a more useful green wavelength of 532 nm (5320 Å). All of the pulsed modes of operation available with the ruby system are also available with Nd:YAG system. The reconstruction of pulsed holograms can be performed with an argon ion laser at 514 nm (5140 Å). Owing to somewhat better thermal properties, continuous-wave Nd:YAG lasers are available with power capabilities well over 50 W (multimode), but their application in holography is still quite limited.

Exposure Controls

Most holographic systems control light by means of a mechanical or electrical shutter attached to the laser or separately mounted next to the laser. More sophisticated systems have photodetectors in the optical system and associated electronics that integrate the light intensity and close the shutter when the photographic plate or film has been properly exposed. Holographic systems that require strobing capabilities use acousto-optic modulators that can modulate the laser beam at rates up to at least 10 MHz and with 85% efficiency. It should be noted that a strobed system with a 5% duty cycle will have an effective brightness of 5% of normal (a 20-mW laser is effectively a 1-mW laser).

Beam Splitters

A piece of flat glass is usually a sufficient beam splitter for a production holographic system designed for recording only. If the system is to be used for recording and reconstruction or for real-time analysis, there are two approaches:

- The less expensive system uses a beam splitter that splits 20 to 30% of the light into the reference beam; a variable attenuator or a filter wheel is used to adjust the reference beam to the proper intensity
- The more expensive approach is to use a variable beam splitter, which consists of a wheel that varies the split from 95-to-5% to 5-to-95% as the wheel is rotated

Beam Expanders and Spatial Filters

Beam Expanders. Expansion of the narrow laser beam is required to illuminate the test object as well as the holographic film. A short focal length converging lens is often used for this purpose, ultimately causing the beam to diverge for distances greater than the focal length of the lens. For high-power pulsed-laser sources, a diverging lens must be used because the field strengths may become so intense at the focus of a converging lens that dielectric breakdown of the air may occur.

Spatial Filters. An unfiltered expanded laser beam usually displays diffraction rings and dark spots arising from extraneous particles on the beam-handling optical components. These rings and spots detract from the visual quality of the image and may even obscure the displacement-fringe pattern. For most CW holographic systems, laser powers are sufficiently low that spatial filters can be used to clean up the laser beam. Spatial filters basically consist of a lens with a short focal length and an appropriate pinhole filter. By placing a pinhole of the proper size at the focal point of the lens, only the laser light unscattered by dust and imperfections on the surfaces of the optical components can pass through the pinhole. The result is a uniform, diverging light field.

Pinhole Size and Alignment Specifications. A good spatial filter uses a high-quality microscope objective lens; a round, uniform pinhole in a foil of stainless steel or nickel; and a mount that allows the quick and stable positioning of the lens and pinhole. A complete analysis of the best pinhole size includes the factors of beam diameter, wavelength, and objective power. If the pinhole is too small, light transmission will suffer, and alignment will be very sensitive. As the pinhole size is increased, alignment is easier to achieve and maintain. As the pinhole size becomes too large, it begins to allow off-center, scattered light to pass through, with the result that the diverged beam will contain diffraction rings and other nonuniformities associated with dust and dirt. The pinhole will then begin to transmit information to construct the diffraction field of the particle. This does not prevent the recording of holograms; it only generates unwanted variations in light intensity. As a general rule, the magnification power of the objective multiplied by the pinhole diameter (in microns) should equal 200 to 300.

The position of the pinhole should be adjusted at a laser power level below 50 mW. A misaligned pinhole at a high power level can be burned by the intense point of light, rendering the pinhole useless. High-magnification spatial filters require the most care. With proper alignment, standard pinholes will function without degradation when the laser output power in watts multiplied by the objective magnification does not exceed 20.

Mirrors

Most holographic mirrors are front-surface coated. Second-surface-coated mirrors are generally unsatisfactory, because of losses at the front surface and the fact that the small reflection that occurs at the front surface generates unwanted fringes in the light field, which interfere with interpretation. Mirrors for holography do not need to be ultraflat. Inexpensive front-surface-coated mirrors are readily available in sizes up to 610 mm (24 in.). Metal-coated mirrors are usually the least expensive, but they can cause a 15% loss of reflected light. Dielectric-coated mirrors have greater than 99.5% reflectivity, but are much more expensive than metal-coated mirrors and are sensitive to the reflection angle. All mirrors, like all other

optical components, require some care with regard to cleanliness. The cleaning of some mirrors is so critical that in many applications it is best to use inexpensive metal-coated mirrors, which can be periodically replaced. The manufacturer should be consulted in each instance as to the proper procedure for cleaning each particular type of mirror. Because mirrors reflect light rather than transmit it, they are a particularly sensitive component in a holographic system. They must be rigidly mounted and should be no larger than necessary.

Photographic Plate and Film Holders

Photographic plate and film holders perform the following two functions:

- They hold the plate (or film) stable during holographic recording
- They permit precise repositioning of the plate (or film) for real-time analysis

The first function is not difficult to achieve, but the second function is. If real-time analysis is not required, glass plates or films will work in almost any holder or transport mechanism. Real-time work requires special considerations. The problems inherent in real-time work can be handled by the use of replaceable plate holders, in-place liquid plate processors, and nonliquid plate processing.

Replaceable Plate Holders. With replaceable plate holders, the photographic plate is placed in the holder, exposed, and removed for processing. After processing, the plate is put back in the holder; the plate must be as close as possible to its original position in the holder to permit real-time analysis. Some plate holders have micrometer adjustments to dial out residual fringes. As a production method, the use of replaceable plate holders is very slow.

In-place plate processing is accomplished by using a liquid-gate plate holder (termed a real-time plate holder), which has a built-in liquid tank with appropriate viewing windows. The plate is immersed in the liquid in the tank (usually water) and allowed to soak for 15 to 30 s. Upon exposure, the tank is drained of the immersing liquid, and the plate is developed in place by pumping in the proper sequence of developing chemicals. After the plate is developed, the developing chemicals are replaced with the original immersing liquid, and the hologram is viewed through the gate of liquid. This procedure not only permits processing of the plate without disturbing its position but also eliminates the problem of emulsion swelling and shrinking, which causes residual fringes in many real-time setups. Plate development can take less than 30 s; total processing time is 1 min or less. Commercial systems are available that cycle the appropriate liquids through the cell as well as provide film advance for holographic films in a continuous-roll format.

Another holographic camera system permitting in-place development uses a thermoplastic recording medium that is developed by the application of heat. Such systems are available from at least two commercial suppliers. One system permits erasure and reexposure of the thermoplastic film plate with cycle times of just under 1 min. The plates can be reexposed at least 300 times. These systems and the high-speed liquid-gate processing systems mentioned above eliminate many of the inconveniences associated with holographic film handling and processing.

Nonliquid Plate Processing. Other in-place processing systems have been devised. Nonliquid plate processing using gases for self-development holds much promise for holographic recording. Photopolymers are promising as production recording media because they can generate a hologram quickly and inexpensively. For one photopolymer film, the photopolymer is exposed at a much higher energy level than is a silver emulsion (2 to 5 mJ/cm² versus 20 μ J/cm² or less for silver emulsions). After exposure, the hologram is ready to use. However, to prevent further photoreaction during viewing, the hologram is fixed by a flash of ultraviolet light.

Lenses

Lenses are required in some holographic systems. If the function of the lens is to diverge or converge a light beam, almost any quality of lens will suffice. However, if precise, repeatable control is desired, the lenses may need to be diffraction limited. Analysis of a proposed holographic system is sometimes best done by trial and error or by use of the best possible components, rather than by attempting a complicated mathematical computation.

Lenses can be antireflection coated if needed or desired. For example, lenses used in pulsed ruby systems for diverging a raw beam should be fused-silica negative lenses with a high-power antireflection coating. Some low-power ruby laser

systems, however, have operated satisfactorily with uncoated lenses. Guidelines for using lenses with ruby lasers are available from the laser manufacturer.

Mounts

Mounts for the holographic components should be carefully chosen. Mounts that require adjustments should be kept to as few as possible. All fixed mounts should be bolted or welded in place. Some attention should be given to mount material; aluminum, for example, is generally a good material, but because of its high coefficient of thermal expansion, an alternative material might be more suitable in a given application. Mounts that are rugged and rigidly built should be selected. Holographic components should be positioned as close to the supporting structure as is practical.

Holographic Tables

Holographic components must be mounted with sufficient rigidity and isolation from ambient vibration to maintain their dimensional relationships within a few millionths of an inch during recording and real-time analysis. As discussed previously, the use of pulsed lasers to generate double-exposure holograms requires very little vibration isolation so long as the separation between exposures is short. When vibration isolation is required, the designer must exercise care in the design of the structure used to support the holographic system in order to isolate the structure from outside excitation. This design involves the three following considerations:

- Building the structure with sufficient rigidity to reduce the deflection of components to within holographic limits
- Building the structure with sufficient damping capacity to absorb excitation energy and to prevent excessive resonant-vibration amplitudes
- Building the structure with sufficient mass to increase inertia and therefore decrease response from outside driving forces

Small, low-cost holographic systems are usually supported by one of a variety of vibration-isolation tables, which float on three or four rubber air bladders or small inner tubes. The holographic components are screwed, clamped, magnetically held, or simply set in place on the table. As the size of the holographic system (and therefore the size of the table) increases, more care is needed to maintain stability. There are three basic types of large holographic tables:

- Honeycomb tables
- Slabs
- Weldments

Honeycomb tables, made of honeycomb-core sandwiched panels, are extensively used for holography. They can range in thickness from 50 mm to 0.9 m (2 in. to 3 ft). The outer skin is usually a ferromagnetic stainless steel, but for increased temperature stability, an outer skin of Invar can be used. Honeycomb tabletops weigh less than 10% as much as a steel table of equivalent rigidity. They can be fabricated from vibration-damping materials to make them acoustically dead. The tables are usually floated on three or four air mounts. Air mounts (generally forming a leg for the table) are large air cylinders with rolling-diaphragm pistons that contact the table. A servovalve inputs or exhausts air at the cylinder to maintain constant height of the leg and keeps the table level as components are moved about. Air mounts provide excellent isolation by virtue of their low resonant frequencies, typically 1 to 2 Hz. The holographic components can be set on the honeycomb table, attached with magnetic clamps, or screwed down utilizing an array of drilled-and-tapped holes in the upper-skin centers.

Most solid tabletops used in holography are flat within 0.025 mm (0.001 in.) or less, while honeycomb tables (1.2 × 2.4 m, or 4 × 8 ft) are flat within 0.10 to 0.25 mm (0.004 to 0.010 in.). This difference does not hamper the performance of most holographic systems.

Slabs are the least costly type of support for a large holographic system. They are usually made from steel or granite and floated on a vibration-isolation system. Many low-cost supports have been laboratory constructed by floating a surplus granite or steel surface plate on an array of tire tubes. It is usually difficult to dampen vibrations that reach the surface of a

slab. For this reason, the performance of a slab degrades when the test objects are large and/or the ambient noise level is high (particularly from air-conditioning systems that emit low-frequency noise). This problem can be minimized by selecting a material (such as gray iron) that has naturally high damping capacity rather than a material that has a ring.

Most components that are attached to three-point mounts need not be rigidly attached to the slab, but other components (and particularly the object being vibrated or otherwise stressed) need to be rigidly mounted to ensure stability. To facilitate the mounting of components, the slab top may require tapped holes, T-slots, or a coating of tacky wax, or it may need to be ferromagnetic.

Weldments are heavily braced frames or plates generally designed as part of a portable or otherwise special system used to analyze very large or unusual test objects. Weldments are generally used where slabs or honeycomb tables are not suitable, although a slab or honeycomb-core sandwich panel may be part of the structure for mounting the components.

Types of Holographic Systems

There are basically two types of holographic systems: stationary and portable. Both will be discussed in this section.

Stationary Holographic Systems

A holographic system is considered stationary when it is of such size, weight, or design that it can be utilized only by bringing the test object and required stressing fixtures to the system for analysis. Stationary systems are usually dependent on building services, requiring compressed air for the vibration-isolation system, electric power for the laser and other electronic components, and running water for processing the holograms and cooling the laser (for example, as required for an argon laser). Most stationary systems operate in a room with light and air control to achieve high stability and the low light levels required for recording, processing, and viewing holograms. As the size of the table increases, the stability requirements become more difficult to satisfy. As a result, the cost of a stationary system generally increases approximately exponentially with object size.

Stationary systems are used in the following cases:

- Production line inspection of small objects
- Where required flexibility in the type and size of test objects is needed for developmental work
- Inspection of a large or awkward structure that cannot be holographed by a portable system

Portable Holographic Systems

A portable holographic system can be moved to the test object and operated with minimal setup time. A portable system built for the Apollo lunar exploration program was designed to record holograms of lunar soil. It was battery powered, weighed 7.89 kg (17.4 lb), and occupied less than 0.017 m³ (0.6 ft³) of area. A portable holographic system used for developmental work, particularly in wind tunnels, has been transported throughout the United States by semitrailer truck. The components of the system are mounted in cabinets or in frames on wheels, and upon arrival at the test site, the system is unloaded and set up in several hours. A portable system used to inspect sandwich-structure helicopter-rotor blades is shown schematically in Fig. 5; a portable system used to inspect sandwich panels is shown in Fig. 10.

Fig. 10 Portable holographic analyzer for the inspection of sandwich panels with use of vacuum stressing. See description in text.

Reflection Holographic Systems. In a simplified type of portable system, a tripod-mounted laser and spatial filter project light directly through a holographic plate fastened to the test object. A reflection hologram is formed by interference between the light traveling through the plate and the light reflected back to the plate from the object. In this system, the reference beam and the object beam strike the emulsion from opposite sides of the plate, resulting in the reconstruction of a virtual image produced by reflection. This configuration differs from the holographic systems described earlier, in which the two recording beams strike the plate from the same side and, during reconstruction, the virtual image is produced by transmission.

An important consideration in designing reflection holographic systems is that reflection holograms are more sensitive than transmission holograms to photographic emulsion shrinkage, which may take place during the development and drying processes. This shrinkage causes the image formed during reconstruction to be produced at a slightly shorter wavelength (a hologram recorded with red laser light will reconstruct best in yellow or green light). Unless the reconstructing light matches this shorter wavelength, the image will be quite faint. Therefore, white light, which contains all the required wavelengths for efficient image production, is often used as the reconstructing reference beam instead of laser light.

Because, as described above, the film plate also serves as a beam splitter and can be mounted to the test object itself, reflection holographic systems can be quite insensitive to object vibration. The major critical stability requirement is the relationship between the object and the holographic plate fastened to it. If the emulsion shrinkage is fairly uniform and the holographic plate is in close proximity to the test object, the image formed will be bright and clear. The plate must be dried carefully, however, to avoid variations in emulsion thickness, which would cause variation in the color of the image. Because the diffraction of light changes with color, variations in color will cause smearing of the image and loss of resolution. The greater the distance from the object to the plate, the greater the smearing.

Portable systems can be used in the following cases:

- Field inspection
- When the size or configuration of a test object is such that it is more practical to attach the holographic system to the object than vice versa
- When the test object is in an environment or in a structure required as part of the experiment

Portable holographic systems are usually designed to inspect a specific part or a range of small parts. The questions that establish criteria for designing a portable system are the following:

- How is the system to be powered?
- How is stability between the system and the test object to be maintained both during and between exposures?
- How can critical adjustments be made or eliminated?
- How is the photographic plate to be handled and processed?
- How can the holographic components and the stressing fixture be designed into a workable system within the definition of portable?

Optical Holography

Typical Holographic Testing Applications

Among the applications for which holographic testing is utilized are the following:

- Inspection of sandwich structures for debonds
- Inspection of laminates for unbonded regions
- Inspection of metal parts for cracks
- Inspection of hydraulic fittings
- Measuring of small crack displacements
- Vibration analysis of turbine and propeller blades
- Holographic contouring
- Characterization of composite materials

Optical Holography

Revised by James W. Wagner, The Johns Hopkins University

Inspection of Sandwich Structures for Debonds

A sandwich structure usually consists of face sheets separated by a lightweight core. The face sheets are designed to carry in-plane loads; the core is designed to stiffen the face sheets and prevent them from buckling and to carry normal loads in compression or shear. The core can be a solid material, such as balsa wood, or a cellular material, such as foam plastic or honeycomb construction. The face sheets and core are usually held together by an adhesive or braze material.

The extensive use of sandwich structures in widely varying applications has created some unusual inspection problems. The main area of interest is the quality of the attachment of the face sheets to the core; large areas of structures must be inspected inexpensively for unbonded or unbrazed areas (debonds) and for poorly bonded or brazed regions. The inspection for poorly bonded or brazed regions has not yet been satisfactorily accomplished on a production basis, but is currently the subject of various research programs. A secondary area of interest is the edge-closure assembly, which surrounds the sandwich structure. The configuration of the closure varies depending on whether the sandwich is brazed or bonded and on the types of materials involved. Sandwich structures cause inspection problems because of the number of parts being joined together and the abrupt changes in thickness or solidity of the assembly. An additional complication arises in designing a holographic inspection system for sandwich structures in that structures range in area from several square inches to several square feet and their contours vary from simple flat panels to complex curved shapes, such as helicopter rotor blades. Both sides and all edges of the structures must be inspected.

When inspecting sandwich structures, it is necessary to determine which stressing technique or combination of techniques will best detect the types of flaws likely to be present. If several techniques are chosen, it must be decided whether to apply them simultaneously or sequentially. The two stressing techniques that have been found to work well for the routine inspection of sandwich structures are thermal stressing (Fig. 11) and vacuum stressing (Fig. 4), although stress for inspection can be provided by acoustical loading (Fig. 3), fatigue loading (Fig. 5), or impact loading.

Fig. 11 Honeycomb-core panel illustrating the detection of debond by thermal stressing. (a) Section through the region of debond. (b) Same section as in (a) showing bulge in face sheet over the region of debond, caused by gentle heating of the face sheet

Techniques for inspecting sandwich structures are well established and documented (Ref 20). Most inspection of sandwich structures is being done, and probably will be done, using CW techniques, with pulsed-laser techniques being used only for special applications.

Example 1: Detection of a Debond in a Honeycomb-Core Panel With Thermal-Stressing Holographic Techniques.

As an example of holographic inspection using thermal stressing, assume that a honeycomb-core sandwich panel, such as that illustrated in Fig. 11(a), contains a debond. If the face sheet over the debond is gently heated, the region over the debond will become hotter faster because the heat in that region is not conducted away to the core. The result of this differential-temperature field is a slight bulge in the heated face sheet (Fig. 11b). Using either real-time or double-exposure time-lapse holographic techniques, an image will be formed in which the region of the bulge is contoured by a set of fringes representing lines of constant displacement between the two images.

A typical set of fringes caused by a debond in a honeycomb-core sandwich panel is illustrated by the interferogram in Fig. 12, which demonstrates the sensitivity of inspection by thermal stressing. This interferogram was obtained using the double-exposure technique and a pulsed ruby laser, which has a wavelength of 694 nm (6940 Å) (Table 1). Using Eq 3, it can be seen that each fringe, except the first, represents an out-of-plane displacement of $0.694/(2 \sin 90^\circ)$, or about $0.33 \mu\text{m}$ ($13 \mu\text{in.}$). The region above the debond in the panel, which had a face sheet $500 \mu\text{m}$ (0.02 in.) thick and was heated only about 2.8°C (5°F), has a maximum displacement of about $3 \mu\text{m}$ ($120 \mu\text{in.}$), or only about 0.6% of the face sheet thickness.

Fig. 12 Double-exposure time-lapse interferogram of a thermally stressed honeycomb-core sandwich panel showing a fringe pattern (arrow) contouring a region of the front face sheet over a debond. The panel had metal face sheets $500 \mu\text{m}$ (0.02 in.) thick and was heated about 2.8°C (5°F) between exposures, which were made with a pulsed ruby laser. The fringes indicate a maximum displacement over the debond of $3 \mu\text{m}$ ($120 \mu\text{in.}$). The background fringes were caused by general movement of the face sheet due to heating.

Example 2: Holographic Detection of a Debond in a Sandwich Structure Using the Vacuum-Stressing Method.

Inspection by vacuum stressing has also been found to be effective for detecting debonds in sandwich structures. Figure 10 shows the essential components of a portable holographic analyzer for the inspection of sandwich panels. This analyzer consists of two separate sets of equipment: one set for vacuum stressing and holographic recording (Fig. 10a) and one set for holographic reconstruction (Fig. 10b). The holographic recording system is mounted on the top of a hollow supporting structure that rests on the test panel. The recording system contains a 3-mW CW helium-neon laser and, through the use of suitable optical components, encompasses a 460 mm (18 in.) diam circular field of view of the portion of the panel surface beneath the supporting structure.

During an inspection, the vacuum chamber, which is made of fiberglass, is lowered over the recording system until contact is made with the surface of the panel. A first exposure is made of the panel in its unstressed state. A second exposure is made when the internal pressure has been reduced by approximately 7

kPa (1 psi). The pressure of the ambient air in the core voids pushes the face sheets out at unbonded regions. The double-exposure hologram is recorded as a circular field 8 mm (0.3 in.) in diameter on a $16 \text{ mm } (\frac{5}{8} \text{ in.})$ film strip. The film is then advanced, the vacuum is released, the system is moved to the next location on the panel, and the sequence is repeated. The total time required for constructing a double-exposure hologram is usually about 1 min or less. By using a film strip 2030 mm (80 in.) long, it is possible to record a total of more than 200 double-exposure holograms.

A typical commercial holographic analyzer for the inspection of sandwich structures is illustrated in Fig. 13. It consists of a $3.7 \times 2.4 \text{ m}$ ($12 \times 8 \text{ ft}$) table supported on air bearings. On this table is a part-holding mounting plate, which is supported by two 1220 mm (48 in.) diam trunnion plates. The mounting plate can be rotated and translated to view either flat panels or curved shapes. The holographic system usually uses a 50-mW helium-neon laser, but can also use higher-powered argon lasers. The part to be inspected is held in place on the mounting plate by a series of vacuum cups or clamps. Thermal, vibrational, pressure or vacuum stressing can be applied. A part measuring up to $1.5 \times 1.8 \text{ m}$ ($5 \times 6 \text{ ft}$) can be inspected with this analyzer. Other analyzers are available that are designed to handle either smaller parts or larger parts (up to $1.8 \times 6.1 \text{ m}$, or $6 \times 20 \text{ ft}$).

Fig. 13 Commercial holographic analyzer used for the inspection of sandwich structures. See text for description.

Approximately 0.19 or 0.28 m² (2 or 3 ft²) of a part surface can be viewed in a single hologram with the analyzer illustrated in Fig. 13. The exposure and processing of the hologram are controlled automatically by the analyzer. With the 50-mW helium-neon laser, approximately 2.3 m² (25 ft²) of surface can be inspected per hour. Either double-exposure or real-time interferograms can be made with this analyzer. Using the real-time technique, the inspected areas can be recorded by taking still photographs through the hologram or preferably by recording the transient patterns on videotape. Still photographs give an indication of obvious flaws, but far smaller flaws can be detected by an experienced inspector viewing a sweeping fringe pattern. A library of videotapes showing various flaws can be used as a training and qualifying aid. As in other inspection techniques, standards and qualifying procedures must be established. Application and further development of automated fringe interpretation methods could also be used to advantage for this type of inspection.

Optical Holography

Revised by James W. Wagner, The Johns Hopkins University

Inspection of Laminates for Unbonded Regions

Standard optical holographic systems are readily used to identify the presence of flaws in laminated composites and structures. Generally, double-exposure techniques are the most convenient, although both real-time techniques and time-average techniques (for oscillating systems) can also be used. Because the most common flaw in laminates is a lack of bonding, the critical problem is to select the most suitable stressing technique that will reveal the presence of the unbonded region by inducing some differential movement between the bonded and unbonded regions.

Example 3: Holographic Tire Analyzer for Detecting Flaws With Vacuum-Stressing Technique.

An example of a laminated composite is the pneumatic tire, which is constructed of layers of rubber and fabric. (Some of the fabrics used in modern tires contain steel wires.) The commercial holographic tire analyzer illustrated in Fig. 14 is capable of inspecting tires ranging in size up to a maximum outside diameter of 1145 mm (45 in.) at a rate of more than 12 tires per hour when auxiliary semiautomatic options are employed. The inspection procedure uses the vacuum-stressing technique described previously; a double-exposure interferogram is made of each quadrant of the inner walls of the tire undergoing inspection. Flaw anomalies are manifested by minute changes in the inner-wall topography occurring as a result of the pressure differential existing between the unvented tire flaws and the evacuated chamber.

Fig. 14 Commercial holographic analyzer used for the inspection of pneumatic tires. See text for a description of the inspection procedure.

Example 4: Holographic Tire Analyzer for Detecting Defects Using 345 kPa (50 psi) Inflation Pressure.

A different type of holographic tire analyzer employed to obtain the interferogram shown in Fig. 15 used inflation to 345 kPa (50 psi) rather than vacuum stressing. With this analyzer, both of the sidewalls and the tread portion of the tire can be inspected simultaneously for all unbonded regions.

Fig. 15 Double-exposure time-lapse interferogram of a defective pneumatic tire that was stressed by inflation to 345 kPa (50 psi) between exposures. The contoured fringe patterns (arrows) indicate regions of the sidewall and tread where there is no bond between layers of the cured tire. General movement of the tire during inflation caused the background fringes.

Additional Techniques for Stressing Laminates. Other laminates can be stressed by heating (as with printed circuit boards), by ultrasonic excitation, and by the addition and removal of a mechanical load.

Example 5: Holographic Inspection of Coprene Rubber-Stainless Steel Laminate Using Mechanical Loading Technique.

An example of the use of the mechanical-loading method is a simple rubber-steel laminate that was stressed in cantilever bending while clamped along one edge. Holographic exposures made before and after stressing reveal a field of closely spaced fringes (Fig. 16) due to anelastic effects that prevent full recovery. Local perturbations in this field due to an unbonded region between the rubber sheet and the metal substrate can be readily identified as an anomaly in the fringe pattern.

Fig. 16 Double-exposure time-lapse interferogram of a defective rubber-steel laminate that was mechanically stressed between exposures showing a local perturbation in the fringe pattern (arrow) over an unbonded region. The laminate was 125 mm (4.92 in.) long by 90 mm (3.5 in.) wide and was composed of a 0.94 mm (0.037 in.) thick sheet of coprene rubber bonded to a 1.93 mm (0.075 in.) thick sheet of stainless steel. The rubber face was painted with a bright white reflecting paint to aid in holographic inspection.

Optical Holography

Inspection of Metal Parts for Cracks

Optical holographic inspection has not proved to be an effective method for finding even large cracks in metal parts. The primary reason for this is the difficulty of stressing the test object in such a manner as to create a difference in displacement that is easily detectable optically. Speckle-pattern techniques can be useful for the detection of in-plane displacements associated with surface cracks.

In general, only those cracks greater in length than the thickness of the part are detectable by optical holographic inspection. Several stressing methods have been found to be useful, such as mechanical stressing by means of loading fixtures or interference fasteners as well as thermal stressing by means of heat lamps or cold liquids or solids. Either real-time techniques or double-exposure techniques can be used. Also, high-resolution techniques, such as phase stepping and heterodyne holographic interferometry, have been used (see the section "Interpretation of Inspection Results" in this article). Time-average time-lapse techniques are generally not successful for detecting the effects of cracks on vibratory patterns.

Example 6: Holographic Inspection of Hydraulic Fittings to Detect Cracks.

An instance of the successful detection of cracks by optical holography was the inspection of small hydraulic fittings. Radiographic studies using x-rays, eddy current testing, and other forms of nondestructive inspection did not provide reliable detection of these small cracks or sufficient data on crack growth characteristics.

To solve the inspection problem, conventional double-exposure time-lapse holography was employed using a 15-mW helium-neon laser and portable optical components. The plate holder was a conventional static type and held 100 × 125 mm (4 × 5 in.) glass plates. The entire optical system was mounted on a commercial 1.2 × 2.4 m (4 × 8 ft) vibration-isolation (holographic) table.

Inspection consisted of first making a holographic exposure of a fitting held statically in a vise-type clamping fixture. After the first exposure, a mating fitting was screwed into the test fitting to approximate normal in-use loading, and a second exposure was then made on the same holographic plate. The resulting interferogram is shown in Fig. 17. Each interference fringe in this reconstruction represents a displacement between exposures of approximately one-half the wavelength of the helium-neon light ($\lambda = 633 \text{ nm}$, or 6330 \AA), or about $0.33 \text{ }\mu\text{m}$ ($13 \text{ }\mu\text{in.}$). The discontinuity in the fringe pattern indicates that relative motion, or slippage, occurred along the front vertical edge of the fitting during loading. Inspection at still higher loads revealed a small crack along that edge.

Fig. 17 Double-exposure interferogram of a cracked hydraulic fitting. The fitting was stressed between exposures by having a mating fitting screwed into it. The holocamera used a 15-mW heliumneon laser. The discontinuity in the fringe pattern (arrow) was caused by a small crack in the fitting.

The use of optical holographic inspection in this application permitted relatively inexperienced personnel to pinpoint small cracks in several hydraulic fittings and to study the propagation of these cracks under varying load conditions. This brief study program required approximately 6 h of engineering time and no special fixturing or tooling.

Example 7: Small Crack Displacement Measurements Using Heterodyne Holographic Interferometry.

As mentioned above, the small out-of-plane displacements associated with most cracks make it difficult to apply conventional (homodyne) holographic interferometry techniques. Still, small displacements do occur and can be visualized holographically using high-resolution techniques. For example, Fig. 18 shows the results of a heterodyne analysis of a region of a holographic interferogram near a surface-breaking crack. Total displacements of only 5 to 6 nm (50 to 60 \AA) were observed in this case with a background noise floor of about 0.6 nm (6 \AA).

Fig. 18 Results of heterodyne holographic interferometry showing minute displacements adjacent to a surface-breaking crack in a nickel-base superalloy.

A dual-reference, double-exposure recording technique was used where a bending stress was applied to the cracked specimen between the holographic double exposures. The resulting hologram was reconstructed with a 100-kHz frequency difference imposed between the two reconstructing beams so that the intensity of the image varied sinusoidally at a 100-kHz rate.

Although each point on the image varies in intensity at 100 kHz, the relative phase of these oscillations varies from point to point on the image, depending on the amount of displacement recorded between holographic exposures. Therefore, when a small detector is scanned over the image, the phase of its output signal can be compared with some reference phase from another (fixed) point on the object, as shown in Fig. 19. Because a phase difference of 360° corresponds to a single interferometric fringe, the resulting map of phase difference is directly related to surface displacement. Electronic phase measurement accuracy to 0.36° corresponds to $\frac{1}{1000}$ of one fringe. Uncertainties resulting from the effects of speckle and the environment do not permit meaningful measurements below this level.

Vibration Analysis of Turbine and Propeller Blades

Vibration analysis using routine optical holographic techniques can significantly contribute to the inspection and evaluation of turbine and propeller blades in both the design and manufacturing stages (Ref 21, 22, 23). A recommended approach to turbine blade evaluation is the simultaneous holographic recording of both sides of the blade as it is excited into vibration with shaker tables (at frequencies generally limited to less than 50 kHz), air-horn vibrators, electromagnetic drive systems (where blade materials permit), or piezoelectric transducers (bonded or clamped to the blade). By the use of simultaneous recording, information over and above the straightforward recording of vibrational mode patterns can be obtained. Differences in the mode patterns for the two sides of the blade will suggest an absence of structural integrity at

those points, while differences in vibrational amplitude (for example, in hollow blades) can offer a relative measure of blade wall thickness (that is, a check on cooling passage alignment).

Holographic techniques are applicable to all types of blades, both solid and hollow and of almost any size and shape, as well as entire turbine wheels or propeller assemblies. However, some experimental problems may be encountered in the dual-sided simultaneous recording of large parts, thus necessitating a two-step procedure. (Caution must then be exercised to ensure that the driving frequency and amplitude are identical for both of the holograms.)

For blades of reasonable size (up to perhaps 100 to 125 mm, or 4 to 5 in., chord by 460 to 610 mm, or 18 to 24 in., length), the simultaneous recording of both sides of the blade can be accomplished by a standard holographic system through the use of mirrors (taking care to maintain the path lengths of the reference beam and the object beam within the coherence length of the laser). An alternative method of simultaneous recording is to use a dual holographic system. A reasonably compact (1.2×1.2 m, or 4×4 ft) setup of a dual system can be assembled by first splitting the incoming laser beam into two beams (one for each hologram), each of which is subsequently split again into a reference beam and an object beam by a symmetrical arrangement of the various optical components, as shown in Fig. 20.

Fig. 20 Schematic of a compact dual holographic system for the simultaneous recording of both sides of a turbine blade

An example of the type of data that can be obtained by simultaneous recording is illustrated in Fig. 21, which shows interferograms of both sides of a hollow blade whose pressure wall is about 250 to 375 μm (10 to 15 mil) thinner than its suction wall. Although the two interferograms in Fig. 21 were not recorded simultaneously, identical ultrasonic frequencies and amplitudes were used to excite the blade during recording. This produced fringe patterns in solid regions (the leading and trailing edges) that are essentially the same on the front and back surfaces. However, over the hollow region of the blade, the vibrational amplitude on the pressure side is measurably larger (each fringe represents approximately 0.30 μm , or 12 $\mu\text{in.}$, of out-of-plane displacement) than that on the suction side. In addition, the vibrational amplitude increases from the root to the tip of the blade, indicating a decreasing wall thickness for both the pressure and the suction sides. Pressure stressing is an alternative to vibrational excitation for the holographic inspection of hollow turbine blades for detecting weakened structural characteristics.

Fig. 21 Continuous-exposure interferograms of both sides of a turbine blade that were recorded while the blade was being vibrated. The interferograms were recorded at identical driving frequencies and amplitudes, such as might be obtained with the compact dual holographic system shown in Fig. 20. The holocameras used helium-neon lasers.

To establish the most favorable driving force and frequency for a particular blade, a somewhat extensive series of tests is recommended (perhaps including sectioning of the blades) to correlate the results and to establish standards of acceptance. Although such preliminary testing may be costly, for large production runs this inspection procedure could be valuable for accurate wall thickness gaging in thin-wall structures, in which standard ultrasonic pulse-echo techniques are the most difficult to effect.

The ability to observe one entire surface of a large test object at one time, rather than in a series of limited views, is one of the most important benefits of using holography for nondestructive inspection. One entire surface of an 810 mm (32 in.) diam jet engine fan assembly can be recorded in a single hologram (Fig. 22), considerably facilitating the performance of a vibrational-mode analysis that alternatively would require transducers placed over the entire assembly.

Fig. 22 Continuous-exposure interferogram of one side of an 813 mm (32 in.) diam jet engine fan assembly that was excited at a frequency of 670 Hz showing a 4-nodal-diam mode of vibration. The holocamera used a helium-neon laser.

Optical Holography

Revised by James W. Wagner, The Johns Hopkins University

Holographic Contouring

When evaluating the shape of an opaque object, interference fringes are generated on the object that represent depth or elevation contours. These fringes are usually generated most readily by optically interacting two images of the object that have been slightly displaced from one another, although one method simply requires projecting onto the object a set of fringe surfaces whose normals are roughly parallel to the line of sight of the viewer. The three principal techniques for holographic contouring are discussed below.

Multiple-Source Contouring. In the multiple-source technique (which is not really holographic contouring, but rather holographic interferometry), an optical system is used that incorporates a rotatable mirror for steering the object beam (Fig. 23). A fixed contour map of the object can be generated with this system by making two holographic exposures on the photographic plate that differ only by a slight rotation of the object beam steering mirror, which shifts the virtual image of the object-illumination source.

Fig. 23 Schematic of an optical system for multiple-source holographic contouring. Source: Ref 24

Alternatively, a single holographic exposure can be made with the optical system illustrated in Fig. 23, and after processing and repositioning in the plate holder, a real-time contour map of the object can be generated by a similar slight rotation of the object beam steering mirror. In either case, when the system is suitably arranged for proper viewing, the altitude contours on the map of the surface have a separation distance, Δh , given by:

$$\Delta h = \frac{\lambda}{(2 \sin \alpha)} \quad (\text{Eq 10})$$

where λ is the wavelength of the laser light source and α is the angle of mirror rotation. Suitable arrangement of the system requires that the line of sight through the hologram to the object be in the same plane as the angle of rotation of the object beam and be perpendicular to the mean position of the reflected object beam, as shown in Fig. 23. The multiple-source technique has the advantage of providing for an almost unlimited range of contour separations. However, because of the orthogonal illumination and observation directions, shadowing effects are a handicap, and no reentrant surfaces can be contoured by this technique.

Real-Time Contouring. An optical system for the real-time generation of a contour map by the multiple-source technique is shown in Fig. 24. This system uses collimated reference and object beams to generate hologram gratings by means of two successive exposures at different settings of the object beam steering mirror. Subsequent illumination of a hologram grating by only the collimated reference beam produces a simultaneous reconstruction of both the original and the rotated object beams, which propagate and interfere beyond the hologram grating. The spacing of the resulting vertical-standing-wave interference planes is given by Eq 10 and can be readily calibrated by direct measurement of the fringe field on the hologram itself or by exposing a sheet of film oriented at right angles to the propagation direction of the reconstructed object beams and measuring the fringes recorded there. Finally, suitable orientation of the object anywhere in the reconstructed object beams yields a real-time contour map when viewed at right angles to the object beams.

Fig. 24 Schematic of a real-time optical system for holographic contouring using the multiple-source technique.

See text for discussion.

Example 8: Real-Time Contouring of Electroplated Copper Foil Using a Multiple-Source Holographic System.

The multiple-source system shown in Fig. 24 was used in a study of the tensile properties of electrodeposited metal foils. In the course of this study, the shapes of permanently bulged specimens (Fig. 25a) of copper foil 0.0889 mm (0.00350 in.) thick were measured. The bulges, which were 29 mm (1.14 in.) in diameter, ranged from a few millimeters to half a centimeter in height; therefore, a range of sensitivities was needed.

Fig. 25 Example of real-time contouring using the multiple-source holographic system illustrated in Fig. 24. (a) Photograph of bulged specimen of electrodeposited copper foil 0.0889 mm (0.00350 in.). The bulge was 29 mm (1.14 in.) in diameter. (b) Composite of two contour maps. The specimen was rotated between recordings to expose both sides of the bulge. The fringe separation in this map is 0.229 mm (0.00902 in.).

Because of shadowing, only one side or half of the specimen could be contoured at a time, but multiple recordings with the specimen revolved to expose all sides were made and are shown combined in Fig. 25(b). For this contouring, the fringe separation was 0.229 mm (0.00902 in.); other gratings were made for separations up to 5 mm (0.20 in.) and down to 0.1 mm (0.004 in.). Because no high-precision repositioning is required and the reconstructed fringe field is permanent, this represents a convenient and practical means of real-time contouring. However, if a single exposure is recorded in the hologram and is accurately repositioned to provide an initially clear field with appropriately balanced beams, simple adjustments of the object beam steering mirror provide the capability of a real-time variation of the sensitivity (fringe separation) of the contour map when needed.

Multiple-Wavelength Contouring. Constant-range contours measured from an origin at the center of the hologram can be generated with the multiple-wavelength technique (Ref 24). Because a change in wavelength produces changes in position as well as in magnification and the phase of the object images, the multiple-wavelength technique is more complicated than the multiple-source technique. One configuration has been demonstrated in which both the illumination and viewing directions lie along a line through the center of the hologram and the object (Ref 25). This configuration yields fringes with separations, Δr , given by:

$$\Delta r = \frac{\lambda_1 \lambda_2}{(2|\lambda_1 - \lambda_2|)} \quad (\text{Eq 11})$$

where λ_1 and λ_2 are the wavelengths of the two laser light sources. Because λ_1 and λ_2 are not arbitrarily variable, only discrete sensitivities are available, all of which are quite high. However, because of the more normal illumination conditions, the problems of shadowing associated with the multiple-source technique are completely eliminated.

Multiple-Index Contouring. In this technique, the gaseous or liquid medium surrounding an object is changed between successive exposures of the hologram (for double-exposure interferometry) (Ref 25, 26). This changes the optical-path length by slightly altering the index of refraction of the medium and is most readily accomplished by the use of an immersion cell with windows through which the object can be illuminated and viewed simultaneously. In the optical system for the multiple-index technique (Fig. 26), lenses L_1 and L_2 act as a telescope with its viewing direction normal to the cell window. The aperture between the lenses is used to limit aberrations. The hologram can be constructed at any plane to the right of the beam splitter (for example, at the aperture, as shown in Fig. 26). When this system is used, the contour separation distance, Δh , is given by:

$$\Delta h = \frac{\lambda}{2(n_1 - n_2)} \quad (\text{Eq 12})$$

where λ is the wavelength of the laser light source and n_1 and n_2 are the values of the index of refraction of the cell media used for the two exposures.

Fig. 26 Schematic of the optical system for multiple-index holographic contouring

Example 9: Multiple-Index Holographic Contouring Used to Examine Wear of Articulating Surfaces of an Artificial Knee Implant.

Figure 27 shows the results of a multiple-index holographic-contouring technique applied to the lower (tibial) component of an artificial knee implant (Ref 27, 28). The material is a high-density polymer, and the intent of the holographic contouring was to examine the articulating surfaces of these two sockets for wear resulting from *in vitro* testing. Because wear tracks are not visible from the interferometric images, high-sensitivity heterodyne holographic techniques were again applied. Figure 28 shows the results of the heterodyne analysis over a region of one of the knee sockets. From these scans a gouge in the material is clearly observed; the details are revealed upon further amplification of the phase-difference signal (Fig. 28b).

Fig. 27 Dual refractive index contour hologram of an artificial knee implant component

Fig. 28 Results of heterodyne holographic analysis. (a) Surface gouge in a portion of an artificial knee implant. (b) Higher-resolution scanning that reveals details of the gouge

Multiple-Index Method Versus Multiple-Wavelength Method. The multiple-index technique offers results equivalent to those of the multiple-wavelength technique. (Note that if the effective wavelengths in Eq 11 are defined as $\lambda_1 = \lambda/n_1$ and $\lambda_2 = \lambda/n_2$, Eq 11 becomes Eq 12.) The two techniques have the same types of restrictions and advantages with regard to sensitivity, but the multiple-index optical system is easier to arrange. Both techniques can be performed in either the double-exposure or the real-time mode.

Optical Holography

Revised by James W. Wagner, The Johns Hopkins University

Characterization of Composite Materials

The high-speed pulsed holographic interferometry of transient acoustic waves is used to help determine material properties and to identify certain types of defects in graphite-reinforced epoxy laminate sheets (Ref 29).

Example 10: Holographic Interferometry of Composite Sheet Material.

Large-amplitude acoustic waves were generated in the sheet materials by direct laser pulse excitation for thin sheets or by laser detonation of a very small chemical explosive in thicker ones. Double-pulsed holographic exposures were made, with the first exposure at the instant of excitation and the second exposure occurring after several microseconds of delay. The resulting interferograms are shown in Fig. 29.

Fig. 29 Double-exposure pulsed hologram showing displacements associated with large-amplitude acoustic waves traveling in a centrally excited composite sheet

In this case, the composite sheet was six plies thick, with the fibers running in only one direction in each ply. The ply orientation stacking sequence was $0_2-90_4-0_2$.

From the holographic reconstruction, one observes flexural waves (asymmetric Lamb waves) emanating from the point of excitation. They are clearly least attenuated in the directions of the reinforcing fibers. From their velocities, one can compute the flexural stiffness and estimate the effective Young's modulus as a function of direction in the material. Again, in cases where features smaller than a single fringe must be resolved or when it is not practical to use high excitation forces, phase stepping or heterodyne techniques can be applied (Ref 30).

Figure 30 shows the displacements associated with flexural wave propagation in a sheet where the peak displacement amplitude is about one-third of an interferometric fringe. These displacement data were extracted using phase-stepping methods on a hologram in which not even a single complete fringe was observed. With phase stepping, sensitivities to

about $\frac{1}{30}$ of a fringe are readily obtained with ultimate sensitivities to about $\frac{1}{100}$ achievable under near ideal conditions. (Heterodyne sensitivities approach $\frac{1}{1000}$ of a fringe.)

Fig. 30 Surface displacements resulting from Lamb wave propagation in an aluminum sheet. These subfringe displacements were extracted from the holographic interferogram using phase-step (quasi-heterodyne) holographic interferometry.

Appendix: Selection of Holographic Systems

In general, the considerations that apply to the selection of a holographic system are similar to the considerations that apply to the selection of any other major piece of capital equipment. The selection will be based primarily on the ability of the equipment to perform the tasks that are of chief concern. Beyond that, selection will be governed by such factors as the space and support facilities required, personnel and training, system versatility, and cost. This section outlines the advantages and disadvantages of purchasing holography as an outside service and of operating an in-house system.

Contract (Purchased) Holography

An initial approach for a company with little or no holographic equipment or technical skill might be to purchase the holographic work on a contract basis from a company that performs this work as a service. This would probably be the most economical approach for a company that has only a few parts to inspect or wishes to run only a single development program employing holographic analysis.

The advantages of purchasing holographic work are as follows:

- No capital investment and minimal in-house technical skill are required
- The holographic work can be purchased as required, even on a daily or a per-piece basis
- Some companies will conduct holographic developmental work at low cost if favorable results will promote the sale of equipment
- Purchasing holographic work is a good way to test an application prior to investing in equipment and personnel training
- This method allows the buyer to utilize holography with a very short lead time

The disadvantages of purchasing holographic work are the following:

- Test objects must be shipped to and from the service company. Often, the travel of some in-house personnel may also be required for program success
- Contracted holographic work costs may be high, depending on the equipment and personnel required. This charge must be compared with the cost of suitable alternatives
- Personnel of the service company must be educated concerning the holographic techniques and results as applied to the application in question

In-House Holographic Systems

If the amount of work or other factors make it desirable to have in-house capability, a suitable holographic system can be installed. This can be a commercially available system, such as a tire analyzer or a sandwich-panel analyzer, designed to perform only one task; a commercially available system, such as a portable holocamera or a holographic interference camera, designed for a variety of tasks; or a system built in-house from separately purchased or fabricated components.

Assembled Systems

In-house units can be purchased piece-meal or as one complete system.

The advantages of in-house assembly of a system from components are as follows:

- The system can be built to fit specific or universal needs

- In-house engineering talent can be utilized to reduce capital expenditures by 40% or more
- Such a system can utilize readily available components
- Building a system is an excellent learning experience for the novice desiring to make future use of holographic techniques
- The system can be built and modified to match the expanding skills of the operator

The **disadvantages** of in-house assembly are the following:

- Such systems usually require a long lead time to become operational
- Designing and in-house assembly of a system require either developed or purchased technical skill that can be justified only when it is readily available or when many possible applications exist

Purchased Systems

Purchasing a commercial system has the advantage that the vendor can assume complete responsibility for a system to meet the specifications of the buyer. Details of the components do not need clarification in the bid specification. A specification, for example, need simply state that the system shall be capable of finding a flaw in a given part, of a given length, with a specified confidence level.

The purchased system can be either a complete system designed especially for one task or a system designed for a variety of tasks.

Complete System Designed for One Specific Task. The advantages of purchasing a complete system designed especially for one task are as follows:

- Minimum in-house holographic technical skill is required
- A system that has been previously built or designed can be delivered in a short time

The **disadvantages** are the following:

- Special systems are usually expensive because of the labor required for design, construction, and testing. Costs per unit drop rapidly, however, if more than one unit is built
- It may be difficult to modify the system for other tasks, although many holographic components can be removed for use in another system
- A system that must be designed and built for a special task will require a long lead time

Multifunctional Complete System Designed for Numerous Tasks. Although a special system may be the only means for testing a part of unusual design or size, it is often advantageous to purchase a system designed for a variety of jobs. The advantages of this type of system are as follows:

- Such systems can be less expensive than special systems because they are in volume production, which reduces design costs per unit
- Such systems have flexibility in change-over to inspect different kinds of parts. This usually requires little more than changing the stressing fixture
- The buyer is free to make his own setups
- Delivery time is short; some systems can be purchased off the shelf
- Many vendors will train in-house personnel at no additional cost

The disadvantages are the following:

- The system will be limited by the size or weight of the test object it can handle
- The system may not be as stable as a specialized system because of the flexibility required in the optical components and mounts

Speckle Metrology

F.P. Chiang, Laboratory for Experimental Mechanics Research, State University of New York at Stony Brook

Introduction

MEASUREMENT TECHNIQUES or devices traditionally employ either a regular geometric pattern or a constant as a base transducer. The change of the regularity of the pattern or the response of the base is converted into the measured quantity. Rulers, pressure and strain gages, moiré and interferometric methods, and so on, are all representative of these devices or techniques. Since the 1970s, techniques have been developed that employ random patterns as transducers. Measurement is made not by knowing the deviation from regularity but by determining the correlation between two random signals. This has opened a new field of activity in which new measurement instruments are being developed. In the discussion that follows, the basic principle of the random speckle technique will be described, together with its application to the metrological measurement of metals. Speckle metrology is also known as laser speckle photography (LSP).

Laser Speckle Patterns

Speckle patterns occur naturally in everyday life. From the metrological point of view, they did not attract attention until the advent of the laser. When a coherent laser beam illuminates an optically rough surface (that is, not a mirrorlike surface), the reflected wavelets from each point of the surface mutually interface to form a very complicated pattern. The process is analogous to the ripple pattern formed on the surface of a pond that has been disturbed by raindrops. The only difference is that water speckles form on the surface of the pond, but laser speckles fill the entire space covered by the reflected wavelets. A typical laser speckle pattern is shown in Fig. 1.

Fig. 1 Typical laser speckle pattern

Recording and Delineation of Speckle Displacement

The speckle methods that will be described in the following sections originated from a physical phenomenon first observed by Burch and Tokarsky (Ref 1). They found that when two random patterns are superimposed with an in-plane displacement between them and illuminated with a coherent beam of light, the far field diffraction spectrum is that of a single speckle pattern modulated by a series of Young's fringes whose orientation and spacing are identical to those formed by two point sources located at the ends of the displacement vector experienced by the speckles.

When applying the laser speckle technique, a coherent laser beam is used to illuminate a metal surface (or any optically rough surface). Depending on the information sought, one selects a certain section of the resulting volumetric speckle pattern to be photographed by a camera. When the surface is deformed, the speckle pattern moves accordingly. The spatial movement of the speckle is quite complicated and is governed by a set of three equations (Ref 2).

Conceptually, laser speckles can be viewed as tiny particles attached to the surface by rigid but massless wires. They shift as the surface shifts and tilt in much the same way as light rays are tilted by a mirror. The displaced speckles are photographed again on the same film through double exposure, or a separate recording is made and then superimposed on the first one. The two superimposed speckle patterns are called a specklegram. The speckle displacement can be delineated by sending a narrow laser beam at the points of interest and receiving their corresponding far field diffraction spectrum on a screen. The experimental arrangement is shown in Fig. 2(a). The observer sees a circular diffraction halo

(assuming the aperture of the camera lens is circular) modulated by a series of uniformly spaced straight fringes, that is, the Young's fringes. The intensity distribution of the diffraction spectrum can be expressed as follows (Ref 3):

$$I(\mathbf{u}) = 4 \cos k \left(\frac{\mathbf{u} \cdot \mathbf{d}}{2L} \right) I_h(\mathbf{u}) \quad (\text{Eq 1})$$

where \mathbf{u} is the position vector at the receiving plane, $k = 2\pi/\lambda$ with λ being the wavelength of light, \mathbf{d} is the displacement vector at the point of probing, L is the distance between the specklegram and the receiving screen, and I_h is the so-called halo function, which is the diffraction spectrum of a single speckle pattern.

Fig. 2 Pointwise Fourier processing that results in Young's fringes representing the displacement vector at the point of probing. (a) Schematic of the optical setup. (b) Resulting Young's fringe in a diffraction halo

Equation 1 can be converted into (Ref 3):

$$|\mathbf{d}| = \frac{\lambda L}{S} \quad (\text{Eq 2})$$

where $|\mathbf{d}|$ is the magnitude of the displacement vector and S is the fringe spacing.

These fringes represent the displacement vector of a small cluster of speckles illuminated by the laser beam (Fig. 2b). The displacement of the speckles can be converted into the displacement of the specimen, and depending on the experimental arrangement, different information can be obtained.

Measurement of In-Plane Deformation

For this application, the recording camera is directly focused on the flat surface of the specimen. (The method can also be applied to measuring interior in-plane displacement if the material is transparent to the radiation used, as discussed in Ref 4.) Under either a plane-strain or (generalized) plane-stress condition, the speckle movement is largely confined to the plane of the surface. Therefore, the observer again photographs the speckle pattern formed on the surface after the specimen has been subjected to deformation. The resulting specklegram can be probed point by point to yield the displacement information, as described in the section "Recording and Delineation of Speckle Displacement" in this article.

Alternatively, the observer can obtain full-field displacement information by using the following optical spatial filtering scheme. The specklegram is placed inside a convergent laser beam, as shown in Fig. 3(a). The diffraction spectrum at the focal plane is also governed by Eq 1. At the focal plane, a mask with a small hole situated at \mathbf{u} is used to block all light

except that passing through the small aperture. A second lens is used to receive the filtered light and forms an image of the specimen surface, which is now modulated by a series of fringes governed by (Ref 3):

$$|\mathbf{u}| \cos \theta = \frac{nL}{|\mathbf{u}|}, n = 0, \pm 1, \pm 2, \dots \quad (\text{Eq 3})$$

where θ is the angle between the displacement vector \mathbf{d} and the aperture vector \mathbf{u} . Therefore, the fringes are contours of displacement component resolved along the direction \mathbf{u} . Displacement contours along any direction can be obtained by simply varying the direction of the aperture, and the sensitivity of the contour can be changed continuously by sliding the aperture along the direction of the position vector of the aperture. An example of this application is also shown in Fig. 3(b), in which the fringes are contours of opening (that is, vertical) displacement of a cracked aluminum specimen.

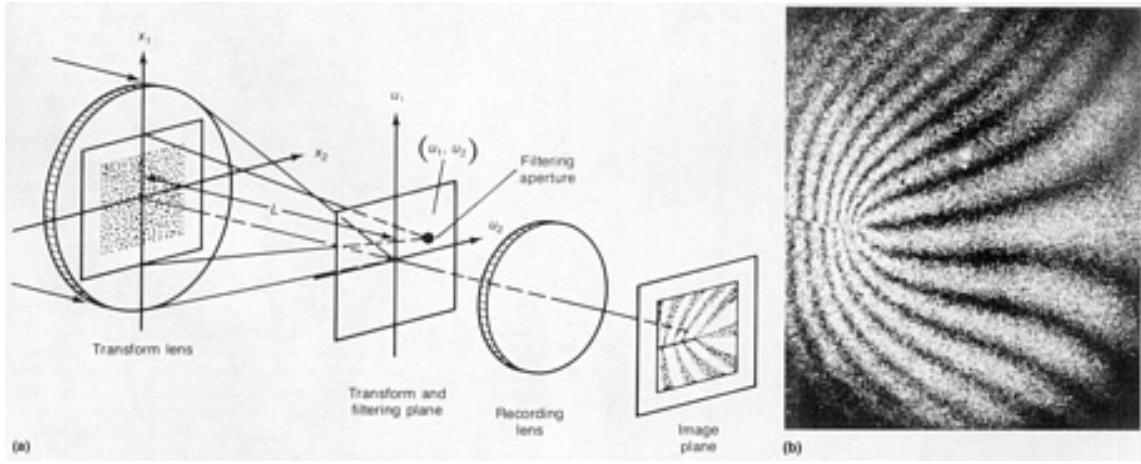

Fig. 3 Optical spatial filtering used to generate full-field displacement contour (isothetic) fringes. (a) Components of optical spatial filter setup. (b) Fringe pattern obtained for an aluminum specimen containing a crack. Each fringe represents 0.005 mm (0.0002 in.) in vertical displacement.

Another example of this type of application is illustrated in Fig. 4, which shows the thermal strain patterns of a heated aluminum plate. The plate is heated with a torch at the lower left-hand corner until it is red hot. It is then left to cool by natural convection. A thermocouple is embedded nearby to monitor the temperature. The patterns are the result of differential thermal strain from the temperatures indicated in Fig. 4. Figure 4(a) shows the displacement of the contour fringes along the x -direction; Fig. 4(b), those along the y -direction. These fringe patterns are governed by:

$$u = \frac{n\lambda L}{u_x}, n = 0, \pm 1, \pm 2, \dots \quad (\text{Eq 4})$$

$$v = \frac{n\lambda L}{u_y}, n = 0, \pm 1, \pm 2, \dots \quad (\text{Eq 5})$$

where u and v are the displacement components along the x - and y -directions, respectively, and u_x and u_y , are the distances of the filtering aperture along the x - and y -directions, respectively. As the plate cools, the temperature tends toward equilibrium, as evidenced by the uniformity of the fringe patterns at lower temperatures. Thermal strains measured by the speckle method compared quite well with the existing data, as shown in Fig. 5.

Fig. 4 Thermal strain determination using laser speckle method. (a) u field. (b) v field. Fringes show the residual strain field between two temperature levels of an aluminum plate torch heated to red hot and allowed to cool by natural convection. Fields u and v are the contour fringe displacements in the x - and y -directions, respectively.

Fig. 5 Comparison between theoretical and experimental thermal strain relaxation at a point as a function of time

Measurement of Out-of-Plane Deformation

The laser speckle method can also be used to measure the out-of-plane deformation of a specimen with a slightly different experimental arrangement. Instead of photographing the speckles on or very close to the surface, one can photograph the speckles at a certain finite distance (a few centimeters, for example) from the surface. When the surface experiences out-of-plane deformation, the spatial speckles are tilted, resulting in speckle displacement at the defocused plane. By recording these speckles before and after deformation, the resulting specklegram is processed in the same way as described in the section "Measurement of In-Plane Deformation" in this article. The resulting fringes are governed by (Ref 3):

$$\frac{\partial w}{\partial x} = \frac{n\lambda L}{2Au_x}, n = 0, \pm 1, \pm 2, \dots \quad (\text{Eq 6})$$

$$\frac{\partial w}{\partial y} = \frac{n\lambda L}{2Au_y}, n = 0, \pm 1, \pm 2, \dots \quad (\text{Eq 7})$$

where $\partial w / \partial x$ and $\partial w / \partial y$ are the slopes of the surface along the x - and y -directions, respectively, and A is the defocused distance. An example of this application is shown in Fig. 6, in which the fringes are the slope fringes $\partial w / \partial x$ of a clamped thin circular plate transversely loaded at the center. A comparison between the experimental result and the theoretical result is also shown in Fig. 6.

Fig. 6 Slope fringes of a clamped circular plate under concentrated load

White Light and Electron Microscopy Speckle Methods

Laser speckle is a natural result of coherent radiation, but speckle pattern can also be artificially created. For example, the aerosol particles of black paint sprayed onto a white surface (or vice versa) create a pattern quite similar to laser speckles.

White Light Method. Another efficient way of creating artificial speckle is to cover the surface with a layer of retroreflective paint. When illuminated by incoherent white light (or any visible light), the individual glass beads embedded in the paint converge the light rays and send them back in approximately the same direction. When imaged and recorded on film, the beads appear as sharply defined, random speckles. These patterns can be used for metrological measurements as well. Any speckle pattern can be used if it yields a distinct pattern and can be recorded for future reference. A few examples are given in Ref 6. These are classified as white light speckles because they are observable under the illumination of incoherent white light. The identical procedures used for laser speckles can be adapted to record and process white light speckles. The only exception is that because white light speckles are located on the surface of the specimen, they cannot be tilted in the same way as laser speckles. However, through the use of defocused photography, depth information can nevertheless be obtained (Ref 6).

The sensitivity of any speckle method is controlled by the sizes of the smallest speckles. The laws of physics dictate that one cannot observe, and therefore record, an object smaller than the wavelength of the radiation that is used to illuminate the object. Therefore, using light in the visible spectrum implies that the smallest observable speckle is about $0.5\ \mu\text{m}$ ($20\ \mu\text{in.}$) in diameter. This is essentially the resolution limit (that is, the smallest measurable displacement) of the speckle method. To increase the sensitivity of the technique, it is necessary to resort to radiation sources having shorter wavelengths.

Electron Microscopy Speckle Method. One option is to use the electron microscope speckle method (Ref 7). Through vacuum deposition or some other type of chemical processing, speckles only a small fraction of a micron in size can be created. These speckles are observable only through an electron microscope. Figure 7 shows two such patterns as observed by scanning electron microscopy and transmission electron microscopy. They were recorded on photographic film and then processed using a laser beam. A typical Young's fringe pattern from a double-exposure electron microscopy specklegram is also shown in Fig. 7. With this approach, the sensitivity of the speckle method can be increased by two orders of magnitude.

Determination of Surface Roughness, Plastic Strain, and Fatigue

When a narrow laser beam impinges on a metal surface, the reflected speckle pattern carries the roughness information of the surface as well. Because plastic strain increases the surface roughness (until the saturation stage is reached), the pattern can also be used to monitor plastic strain. Furthermore, if this technique is used to monitor plastic strain at the tip of a notch, for example, the process of metal fatigue resulting in crack initiation and crack propagation can be ascertained.

Figure 8 shows a typical relationship between surface roughness and plastic strain for an 1100-00 aluminum specimen. As long as the total effective plastic strain is the same, the same surface roughness results irrespective of the path along which the plastic strain is attained.

Fig. 8 Plot of surface roughness versus plastic strain for a polished 1100-00 aluminum specimen

The variation of light intensity of a laser beam reflected from a rough surface can be expressed:

$$\frac{d \langle I \rangle}{\langle I \rangle} |_{V=0} \approx -2g \left(\frac{d\sigma}{\sigma} \right) \quad (\text{Eq 8})$$

along the direction of mirror reflection and:

$$\frac{d \langle I \rangle}{\langle I \rangle} |_{V \neq 0} \approx 2 \left(\frac{d\sigma}{\sigma} \right) - \frac{1}{2} V^2 T^2 \left(\frac{dT}{T} \right) \quad (\text{Eq 9})$$

along all other directions. In Eq 8 and 9, $\langle I \rangle$ is the average intensity, V is the direction of diffracted light, σ is the standard deviation of the surface height function, T is the correlation length of the surface height function, and:

$$g = \left[\frac{2\pi}{\lambda} (1 + \cos \theta) \sigma \right]^2 \quad (\text{Eq 10})$$

where λ is the wavelength of the incident light and θ is the incident angle. Typical diffraction patterns from a metal surface at two levels of plastic strain are shown in Fig. 9 and 10.

Fig. 9 Speckle metrology data for an aluminum 1100 specimen in the original (as-received) state ($\epsilon = 0\%$). (a) Speckle spectrum. (b) Intensity profile of speckle spectrum. (c) Schematic of sampling procedure for testing plastic strain

Fig. 10 Speckle metrology data for an 1100 aluminum specimen subjected to 1.8% plastic strain ($\epsilon = 1.8\%$). (a) Speckle spectrum. (b) Intensity profile of speckle spectrum. (c) Schematic of sampling procedure for testing plastic strain

Both the standard deviation, σ , and the correlation length, T , of the surface height function appear in Eq 9. Therefore, it is more advantageous to use this part of the deflected light for the characterization of surface roughness. This fact is also qualitatively evident from the two diffraction patterns shown in Fig. 9 and 10.

There are many ways to extract information from such a diffraction pattern. One approach is to window out a portion of the higher spatial frequency domain of the diffraction spectrum, digitize it into gray levels (see the article "Machine Vision and Robotic Evaluation" in this Volume), and then calculate the statistical contrast value of the pattern using:

$$CON = \sum (i - j)^2 P(i, j) \quad (\text{Eq 11})$$

where $P(i, j)$ is the probability density of a pair of gray levels occurring at two points separated by a certain distance.

The *CON* value is used to calibrate the measured strains of an aluminum specimen (1100-H14) in tension. The *CON* value increases monotonically with respect to total strain until about 1.2% and plastic strain until about 0.9%. Beyond these points, the *CON* values start to decrease with increased strain. However, in the discussion that follows, it is shown that the *CON* value is nevertheless quite effective in predicting the onset of fatigue crack initiation and propagation.

The *CON* value method is applied to monitoring plastic strains at nine points surrounding the tip region of a saw-cut notch in an aluminum specimen under cyclic bending stress. The geometry of the specimen and the configuration of the points are shown in Fig. 11 and 12, respectively.

Fig. 11 Schematic showing cracks in a fatigue specimen made of 2.3 mm (0.09 in.) thick 1100-00 aluminum. Dimensions given in inches

(a)

(b)

Fig. 12 Schematic of aluminum specimen showing cracks (a) and the nine test points arranged around the tip of the bottom crack (b)

The specimen is mounted in a fatigue machine capable of rendering cyclic bending load. At predetermined cycles, the machine is stopped, and a laser beam is used to illuminate the nine selected points sequentially. The resulting diffraction spectra are received on a ground glass, and a window of their high-frequency region is digitized. A *CON* value is then calculated for each of these digitized images. The results obtained are plotted in Fig. 13.

Fig. 13 Results of using *CON* value of a laser speckle pattern to monitor the onset of fatigue crack initiation and the path of propagation for the sample described in Fig. 12

It is interesting to note that along points 2, 5, and 8, which pinpoint the location of the eventual crack propagation path, the *CON* value increases dramatically at certain cycles of loading. On the other hand, the *CON* value stays almost stationary at the six remaining points, which are only 1.5 mm (0.06 in.) away from the path of crack propagation. This experiment was performed on an aluminum specimen with an initial surface roughness of $0.7 \mu\text{m}$ ($28 \mu\text{in.}$). Similar results were obtained for specimens of other initial roughnesses.

Speckle Metrology

Future Outlook

The speckle method is a relatively new entry in the arsenal of metrological techniques, and it is still evolving. Current research is emphasizing the use of automation in speckle metrology (Ref 8). Researchers are focusing their efforts on two promising techniques. One is the automatic processing of the Young's or full-field fringes, and the other consists of digitizing the speckles and processing them directly. The latter is very appealing because it would eliminate the use of photographic film. However, with the current technology, the solid-state detector does not yet have resolution comparable to that of a photographic emulsion. Other research efforts have been geared toward utilizing a combination of speckle technique and holographic interferometry (Ref 8).

Acoustical Holography

Revised by B.P. Hildebrand, Failure Analysis Associates, Inc.

Introduction

ACOUSTICAL HOLOGRAPHY is the extension of holography into the ultrasonic domain. The principles of acoustical holography are the same as those of optical holography (see the article "Optical Holography" in this Volume) because the laws of interference and diffraction apply to all forms of radiation obeying the wave equation. Differences arise only because the methods for recording and reconstructing the hologram must accommodate the form of radiation used. This need to accommodate the form of radiation restricts the practical range of sound wave frequency that can be used in acoustical holography, as discussed later in this article.

At present, only two types of basic systems for acoustical holography are available:

- The liquid-surface type
- The scanning type

These utilize two different detection methods, and these methods in turn dictate the application of the systems to nondestructive inspection. Neither of these two types of systems relies on the interferometric techniques of optical holographic inspection, in which information on flaws at or near the surface of a test object is obtained from the pattern formed by interference between two nearly identical holographic images that are created while the object is differentially stressed. Instead, systems for acoustical holography obtain information on internal flaws directly from the image of the

interior of the object. The principles of flaw detection by ultrasonic waves, as well as the equipment used, are discussed in the article "Ultrasonic Inspection" in this Volume. Ultrasonic holography is discussed in detail in Ref 1.

Acoustical Holography

Revised by B.P. Hildebrand, Failure Analysis Associates, Inc.

Liquid-Surface Acoustical Holography

The basic system for liquid-surface acoustical holography is similar to the basic system for optical holography except for the method of readout.

Acoustical System. In liquid-surface systems (Fig. 1), two separate ultrasonic transducers supply the object beam and reference beam, which are both usually pulsed. The two transducers and the test object are immersed in a water-filled tank. The test object is positioned in the object plane of an acoustic (ultrasonic) lens, which is also immersed in the tank.

same region of the liquid surface as the object beam, where the wave fronts interfere. The pressure of the beams distorts the liquid surface in this region, levitating portions of it to form a static ripple pattern that acts as a relief hologram. Pulsed ultrasonic beams are used more often than continuous beams. With pulsed beams, the time of arrival of the reference beam at the liquid surface can be varied to compensate for any variations in transit time of the object beam as it traverses the test object and for any significant differences in the path lengths of the beams; this ensures that both beams will arrive at the liquid surface at precisely the same instant to form the ripple pattern.

A water-filled isolation tank is situated inside the immersion tank and serves to prevent ambient vibrations from interfering with the formation of the hologram. A second reason that pulsed ultrasonic beams are used more often than continuous beams is to avoid the creation of standing waves in the immersion tank that would make isolation more difficult.

Although liquid-surface acoustical holography is ideally suited to the use of the ultrasonic object beam in the transmission mode, theoretically there is no reason that the beam cannot be used in the reflection mode to form the image. Practically, however, the high level of object beam intensity and the high quality of object beam transducer required for reflection-mode operation prevent the liquid-surface system from being effective in this mode.

Optical System. In contrast to optical holography, in which the holographic pattern is photographed and the resulting hologram is used to diffract light, in acoustical holography the ripple pattern on the liquid surface is used directly as a grating to diffract light. Therefore, this is a real-time system. The image is reconstructed from the hologram by reflecting a beam of coherent light from the ripple pattern in the isolation tank (Fig. 1). The beam is generated by a laser and passes through an optical system before illuminating the ripple pattern. When a pulsed laser is used, the timing of its pulse is coordinated with the timing of the ultrasonic pulse so that the liquid surface in the isolation tank is illuminated only when there is a stable ripple pattern present. The zero order of diffracted light carries no useful information, so it is blocked by an optically opaque stop. The first two orders of diffracted light carry the image; after the beams are passed through spatial filters, one might be used for photography and the other for television pickup or other purposes. Methods of readout are discussed in greater detail in a later section of this article.

Object Size and Shape. The size of test object that can be completely imaged at any instant is limited by the size of the object beam transducer and lens (typically to a maximum of 152 mm, or 6 in., in diameter). For large test objects, a large object beam transducer and lens must be used, or the test object must be translated through the object beam. Translation in one direction is used for narrow objects; wide objects require translation in two directions. A large, thick object requires translation along the lens axis, as well as along the two other axes, in order to inspect the entire volume of the object. This is because at any instant only a thin segment of the object is in the object plane of the lens and therefore is imaged.

Despite the physical limitations imposed by liquid-surface acoustical holography, there are many inspection problems that can be accommodated. The fact that the system is in real time allows large test objects to be moved through the object plane fast enough to permit high inspection rates. Strip products are especially suitable for inspection by liquid-surface acoustical holography because they are essentially two dimensional and can easily be translated through the object plane. This type of arrangement is shown in Fig. 2. Small parts can be moved through the object plane in a similar manner by the addition of a conveyor belt.

Fig. 2 Schematic of the acoustical portion of a liquid-surface acoustical holography system that is arranged to inspect strip products. The optical portion of this system is identical to that in Fig. 1

The system is usually pulsed at a rate compatible with television frame rates. Typically, 60 holograms per second are produced, which yields flicker-free television images. Because pulse lengths are generally 50 to 300 μ s, strip velocities of 50 to 300 mm/s (2 to 12 in./s) are possible without blurring. With this arrangement, a photograph of one of the holograms of the moving object can be taken at any time by setting the shutter speed of the camera at $\frac{1}{60}$ s.

Sensitivity and Resolution. The sensitivity of liquid-surface systems is fixed somewhat by the necessity to produce a ripple pattern on the liquid surface. For a typical system, the minimum intensity of the ultrasonic beams that can be detected is about 10^{-3} to 10^{-6} W/cm².

The detail that can be resolved by liquid-surface acoustical holography is determined by the focal length and linear aperture of the ultrasonic lens and the wavelength of the ultrasonic beam through the use of the formulas:

$$\Delta x = 1.22\lambda (f/A) \quad (\text{Eq 1})$$

$$\Delta z = 2\lambda (f/A)^2 \quad (\text{Eq 2})$$

where Δx is the resolution in the object plane (that is, lateral resolution), Δz is the resolution perpendicular to the object plane (that is, depth resolution), λ is the ultrasonic wavelength in the immersion liquid, f is the focal length of the ultrasonic lens in the immersion liquid, A is the linear aperture (diameter) of the ultrasonic lens, and f/A is the f -stop number of the ultrasonic lens. For an $f/3$ lens and a frequency of 5 MHz, flaws in steel or aluminum should be resolved to about 1 mm (0.04 in.) transversely and about 5 mm (0.20 in.) in depth; that is, small flaws separated by 1 mm (0.04 in.) transversely or by 5 mm (0.20 in.) in depth can be individually seen, and the size of large flaws can be measured to an accuracy of 1 mm (0.04 in.) transversely and 5 mm (0.20 in.) in depth.

The values of f -stop number for the ultrasonic lenses used in liquid-surface systems are typically 2 to 3. Although the resolution of a system increases with the frequency of the ultrasound used, absorption and scattering of the ultrasound also increase, so that for most industrial testing the frequency range is limited to between 3 and 7 MHz. Sometimes 1 MHz is used, as for rubber products.

Acoustical Holography

Scanning Acoustical Holography

The basic system for scanning acoustical holography is shown in Fig. 3. No reference beam transducer is required in this system, because electronic phase detection is used to produce the hologram; that is, the required interaction (mixing) between the piezoelectrically detected object beam signal and the simulated reference beam signal occurs in the electronic domain. A pulser circuit (consisting of a continuous-wave oscillator and a pulse gate that is triggered by an electronic clock) and a power amplifier feed a single focused ultrasonic transducer that is scanned over an area above the test object while alternately transmitting and receiving the ultrasonic signals. The transducer and the test object are immersed in a water-filled tank or coupled by a water column.

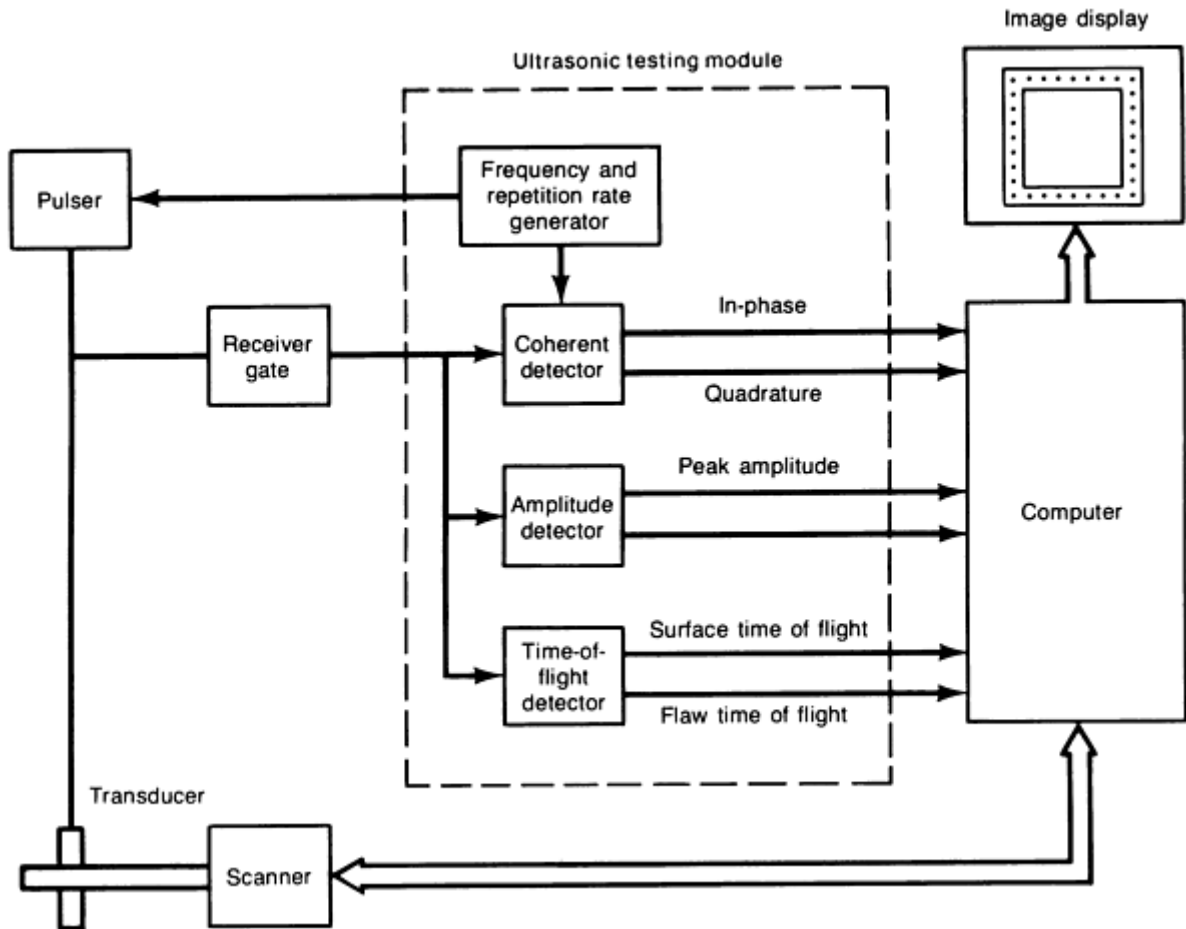

Fig. 3 Block diagram of a commercial ultrasonic and light detection system with capability for A-scan, B-scan, and C-scan imaging and holography

The signal is pulsed so that time gating can be used to reject undesired surface echoes. The pulse length can be set to any desired value from a few periods of the wave frequency to an upper limit of 50% of the time between successive pulses. Long pulse lengths are used to examine regions lying deep within the metal, while short pulse lengths are required for the regions near the surface so that transmitted energy is not mixed with reflected energy. The practical limits of the transducer in a commercial system are a wave frequency of 1 to 10 MHz, a pulse length of 5 to 20 μ s, and a pulse-repetition rate of 500 to 1000 per second. The frequency band of a given transducer is relatively narrow ($\pm 5\%$ of the mean frequency).

The transducer is positioned so that its focal point is at the surface of the test object. In this way, the pulse enters the object and travels through it as a spherical wave front diverging from a point on the surface. Because of refraction at the water/metal interface, the solid angle formed by the conical beam of energy in the metal will be greater than that formed by the focused conical beam from the transducer. This is illustrated in Fig. 4 by a longitudinal wave ultrasonic beam focused at the surface of a steel test object and angled to produce shear waves in the steel. In this situation, the range of angles of incidence must lie between 15 and 27° to produce only shear waves in the steel, and this range of angles will

produce a 47° cone of shear-wave energy in the steel. (Refraction at water/metal interfaces is discussed in the article "Ultrasonic Inspection" in this Volume.)

Fig. 4 Diagram of refraction of a longitudinal wave ultrasonic beam focused on a water/steel interface at incident angles that produced a shear wave beam in the steel

Either longitudinal or shear waves can be used in the scanning system illustrated in Fig. 3. For the longitudinal wave mode, the transducer is oriented parallel to the object surface; for the shear wave mode, the transducer is oriented at the appropriate angle of incidence. With either mode, the wave travels through the object to a flaw, where some of the energy is reflected back to the transducer. This reflected signal is passed through a transmit-receive switch to a gate that is triggered by the electronic clock through a time-delay circuit adjusted to compensate for the water-path transit time. This gate is adjusted in delay and width so that it will pass the reflections from the particular thin segment of the object under examination during the scan and will reject all others.

The reflected signal is split and sent to two balanced mixers, which are also fed by signals derived from the oscillator. These signals are phase shifted by 90° from each other. The outputs of the two mixers are therefore equivalent to the sine and cosine Fourier coefficients of the reflected signal. These coefficients are complete descriptors of the phase and amplitude of the signal reflected by the flaw and thus constitute a hologram.

The outputs of the balanced mixers are sampled, converted to digital numbers by an analog-to-digital converter, and stored in the memory of a personal computer. Thus, the result of a two-dimensional scan of a planar surface is a matrix of complex numbers recorded on the computer disk.

Reconstruction. The results of the detection procedure described above constitute a measurement of the reflected wave front in the scan plane. Because this wave front resulted from the propagation of the reflected sound from the flaw, it must have propagated to the scan plane. Therefore, it should be possible to obtain an image of the flaw by propagating the wave front back to its source. This is done by computer in the following sequence:

- Compute the two-dimensional Fourier transform of the detected wave front as represented by the matrix of Fourier coefficients

- Multiply the transformed data by a complex propagator, the value of which is determined by the distance to the desired image plane
- Compute the inverse Fourier transform of the back-propagated data to return to image coordinates
- Display the magnitude of the resultant matrix of complex numbers representing the image

All these steps can be accomplished in 20 s on a personal computer interfaced with an array processor. The image is displayed on a high-resolution black and white or color monitor.

Because there is no conversion of wavelengths, as there was in the original optical reconstruction method, there is no image distortion. Therefore, the relationship between the size of the image and the size of the object is simply the magnification factor of the display.

Object Size. Although the scanning system is too slow to be useful for the total inspection of large objects, taking about 10 min for a 152 mm (6 in.) square hologram, the real-time advantage held by the liquid-surface system will disappear when piezoelectric arrays and associated electronics become available, because electronic scanning can then be used.

Sensitivity and Resolution. Because the scanning system uses a piezoelectric element as a detector, it is more sensitive than the liquid-surface system by a factor of about 10^6 . For a typical scanning system, the minimum intensity of ultrasonic beam that can be detected is about 10^{-12} W/cm². Mainly because of its much greater sensitivity, scanning acoustical holography appears to hold more long-term promise for the nondestructive inspection of metal products than does the liquid-surface system. It also provides an image of the flaw for subsequent determination of both size and depth within the resolving capacity of the system, which is obtainable from Eq 1 and 2 using the f -stop number of the focused transducer. Transducers having an f -stop number as low as 2 are available for operation in the longitudinal wave mode.

Commercial Liquid-Surface Equipment

A schematic of one type of commercially available system for liquid-surface acoustical holography is presented in Fig. 5. The standard size of the effective object field in this system, which is dependent on the diameters of the two transducers, is 114 mm ($4\frac{1}{2}$ in.) in diameter; test objects larger than this can be inspected by moving them through the object field.

Fig. 5 Schematic of the acoustical and optical systems in the equipment for liquid-surface acoustical holography shown in Fig. 6

This system is well stabilized against vibration through the use of an object tank, a transfer tank, and an isolation tank. The ultrasonic beam is relayed by acoustic lenses from the object tank to the transfer tank through an acoustic window that connects them. The beam is then relayed by an acoustic reflector to the isolation tank, where the holographic ripple pattern is formed. Although the acoustic window permits transfer of the ultrasonic beam, it forms an effective barrier to the transfer of gross movements from the object tank to the transfer tank, where they could disturb the isolation tank and therefore the ripple pattern.

The pulsed object beam transducer, which is typically 127 mm (5 in.) in diameter, emits a wave train several hundred wavelengths long (100 to 300 μ s in duration) 60 times per second. Therefore, the acoustic framing rate is 60 Hz. Similar wave trains are emitted by the reference beam transducer and are delayed in time to arrive at the liquid surface in coincidence with the object beam. The delay time, controlled manually by the operator, depends on the position of the object beam transducer and the thickness of the metal object being examined. The reconstructed image is continuously displayed on the closed-circuit television monitor or on a ground-glass screen.

This system is essentially stationary because the imaging tank must be leveled and the optical system correspondingly aligned and because the system is quite large and heavy. Typical dimensions of the equipment are indicated in Fig. 6. It weighs approximately 450 kg (1000 lb).

Fig. 6 One type of commercially available equipment for the inspection of small metal objects by liquid-surface acoustical holography. Dimensions given in inches

Equipment with a configuration other than that shown in Fig. 5 and 6 has been designed for particular applications. Figure 7 illustrates an alternative configuration used in a piece of liquid-surface equipment designed for the examination of metal strip. This strip moves continuously through the immersion tank by means of entrance and exit water seals. The dimensions of this equipment are shown in Fig. 8. Normally, this equipment operates at 3 to 5 MHz, but frequencies of 1 to 9 MHz can be used. The equipment is designed so that neither mechanical vibration nor electrical static is detrimental to its proper functioning.

Commercial Scanning Equipment

Commercially available equipment, such as that described in Ref 2, for inspection by scanning acoustical holography is often packaged in several units for portability. Figure 9 shows some of the components in one type of commercial system. Each of these units is readily transportable by one or two persons.

Fig. 9 Key components of a commercially available holography system: personal computer, ultrasonic unit, and scanner

The attachment fixture is designed to hold the scanner in position even on surfaces with complex contours. The fixture permits preadjustment of the focal plane of the transducer. After the attachment fixture is in place and aligned, the scanner is mounted on it. The scanner is digitally controlled and is capable of a raster scan pattern in either the x or the y direction. There are six settings of index spacing that can be selected for successive scans: 0.15, 0.30, 0.46, 0.60, 0.76, and 0.91 mm (0.006, 0.012, 0.018, 0.024, 0.030, and 0.036 in.). The largest area that can be recorded in a single hologram with this scanning system is about 305 mm (12 in.) square. However, by systematically repositioning the scanner, much larger areas can be examined.

A series of 25 mm (1 in.) diam transducers with 102 mm (4 in.) focal lengths is used in conjunction with this scanner. Each transducer has a different characteristic operating frequency, so that inspections can be made using any appropriate frequency within the range of 0.5 to 10 MHz. The transducer and bubbler can be oriented for either straight-beam or angle-beam testing. A signal gate in the reflection-signal processor unit can be adjusted to reject reflections from all depths in the object except that under examination. Both the gate width and the gating delay are readily adjustable.

Some models of this equipment also provide switch selectability among A-scan, B-scan, and C-scan modes of display, as well as a combination B-scan and C-scan mode of display that presents an angled view of the flaw image. This angle can be varied to enhance visualization of a flaw (see the article "Ultrasonic Inspection" in this Volume for a description of A-scan, B-scan, and C-scan ultrasonic display modes). The three display modes are illustrated in Fig. 10 for a test block with flat-bottom holes that simulate flaws. The A-scan display was obtained on an oscilloscope screen. The amplitude of the reflected signal is displayed in the vertical direction; time of signal flight, which is proportional to depth in the test block, is displayed horizontally. The B-scan display was obtained by a reconstruction of the hologram produced by orienting the transducer for angle-beam testing, which provided essentially a profile of the region being examined (in this case, the row of five holes in the straight portion of the "D"). The C-scan display was obtained with the transducer oriented for straight-beam testing. The pseudo-three-dimensional image was obtained by the reconstruction of B-scan and C-scan holograms combined.

Acoustical Holography

Revised by B.P. Hildebrand, Failure Analysis Associates, Inc.

Comparison of Liquid-Surface and Scanning Systems

The outstanding feature of the liquid-surface system of acoustical holography is that it provides a real-time image, while the image provided by the scanning system requires reconstruction. The real-time feature makes the liquid-surface system suitable for the rapid inspection of large amounts of material on a continuous basis. In contrast, inspection with the scanning system is relatively slow. Photographic or videotape records for later study can be made with either system.

The prominent feature of the scanning system is its ability to determine accurately the position and dimensions of flaws lying deep in opaque test objects, especially when only one side of the object is accessible. (In contrast to the scanning system, the liquid-surface system is usually operated in the transmission mode, which requires access to both sides of the test object.) Although both systems offer about the same resolution, the sensitivity of the scanning system is greater by a factor of about 10^6 . The excellent flaw-measuring ability of the scanning system can be used to characterize the flaws detected previously by faster inspection methods, such as scanning with a conventional ultrasonic search unit.

Another important feature of the scanning system is that the commercial equipment for this system is usually transportable, while liquid-surface equipment is usually stationary. In addition, scanning transducers can be coupled to very large test objects by water columns, while inspection by the liquid-surface system usually requires that the test objects be small enough to be placed in a water-filled tank and completely immersed.

A useful advantage of the scanning system is its capability for selectively producing either longitudinal or shear waves in the volume of metal under examination through adjustment of the angle of incidence of the incoming ultrasonic beam. The liquid-surface system is limited to straight-beam testing, which produces only longitudinal waves.

The scanning system can also be used for accurate surface contouring. Even surfaces inside vessels can be contoured, without appreciable loss in surface detail, by the use of a scanning system placed outside the vessel.

Acoustical Holography

Revised by B.P. Hildebrand, Failure Analysis Associates, Inc.

Readout Methods

The readout portion of an acoustical holography inspection system provides the means by which the acoustically derived images generated during the reconstruction process are rendered visible for observation and analysis. A variety of methods are available to accomplish this end. One of the most rudimentary but effective methods consists of projecting the image onto the surface of a ground-glass screen for direct viewing. For optimal viewing of the screen, however, the test results must be observed in a darkened area or through a hood that has been placed over the screen to shield out ambient light.

If a permanent record of the test results is required, a loaded film holder can be substituted for the ground-glass screen to record the projected image photographically. This elementary photographic approach requires control of the film-exposure time interval. Exposure-time control can be effected by:

- Simply turning the laser on and off
- Opening and closing a diaphragm or electro-optical shutter placed directly in front of the laser or light source
- Blocking and passing the laser beam with a hand-held piece of cardboard or any other optically opaque substance
- Removing and inserting a rectangular light shield located immediately in front of the film plane

An alternative and more convenient approach is simply to substitute a conventional photographic camera for the film holder. Polaroid films, because of their very short processing times (15 s per individual exposure for black-and-white films) and their ease of usage, have been extensively used for holographic recording. This type of film is available as individual 4×5 in. sheet films, 3×4 in. film packs, and 3×4 in. rolls.

Television Readout. The use of a closed-circuit television system for image readout has the following useful advantages:

- When making real-time observations, the necessity for direct viewing through laser-illuminated screens, which can be tiresome to the eye, is obviated
- A magnification of the image, which is limited only by the size of the monitor screen, is realized without the usual attendant loss in intensity (attributed to the inverse-square law)
- Permanent records of the monitor displays can be made photographically or on videotape
- Special devices can be inserted in the electronic circuits for image enhancement

Time-invariant (steady-state) monitor displays can be photographically recorded with any conventional still camera. If the display varies with time--which is possible with acoustical holography--or if the recording of a sequence of motionless images is desired, the imaging data can be effortlessly recorded on videotape. A movie camera can also be used for this purpose, provided it is accurately synchronized with the monitor display. In both cases, an audio track can be added to describe the nature of the recording. From a recording standpoint, a videotape recorder offers the following advantages:

- The recording medium does not have to be chemically processed, as movie film does
- Playback of the imaging data can immediately follow the recording phase
- The recording medium is erasable and reusable
- Recordings can be made in full color as well as in black and white
- Many videotape recorders are equipped with a variable-frame-rate feature that enables the motion to be slowed to any speed or stopped

Electronic image enhancement can take several forms. By means of a display technique referred to as level slicing, points of uniform intensity in the input image can be displayed as contours. These contours are used in pairs to form the boundaries of bands corresponding to the extremities of an intensity window of finite but variable width. On a black-and-white monitor, the bands are discernible as different shades of gray; on a color monitor, as distinct differences in hue.

Other display formats include isometric and profile displays. Not only can regions within the same image be investigated, but comparisons can be made between two independently selected images to determine the existence of differences in image content. The image signals can also be digitized to permit a better quantitative analysis of the imaging data. Once digitized, the data can be fed into a computer for storage, recall, and subsequent numerical analysis. The nature of the inspection problem, the capabilities of the acoustical holographic approach, and the financial resources available are prominent factors in determining the degree of analytical sophistication to which the data will be subjected.

Acoustical Holography

Revised by B.P. Hildebrand, Failure Analysis Associates, Inc.

Calibration

In conventional ultrasonic systems, the amplitude of the flaw signal is compared to the amplitude of the signal from a standard discontinuity in a test block made of metal similar to that of the test object (see the article "Ultrasonic Inspection" in this Volume). This technique, however, is restricted because signal amplitude depends on the orientation and roughness of the flaw, not simply on its size. In contrast, an acoustical holographic system provides a series of two-dimensional images at different depths. As long as sufficient ultrasonic energy is received to produce an image, the size (and shape) of the flaw can be determined directly from the image. This direct determination provides a better estimate of size than that obtained from conventional ultrasonic systems, which determine size primarily from the total integrated sound energy reflected by the flaw and returned to the transducer. In fact, the flaw image produced by acoustical holography is the most precise characterization obtainable by any nondestructive inspection system used singly. Although the image produced by acoustical holography is not compared to standard discontinuities in test blocks in the same way that comparisons are made in conventional ultrasonic systems, test blocks are required to verify the sensitivity and resolution of the system.

Test Blocks. Figure 11(a) shows an aluminum alloy 1100-F test block that has been used for verification of the sensitivity and lateral resolution of a scanning acoustical holography system (Ref 3). This block contains 15 flat-bottom holes, 3.18 mm (0.125 in.) in diameter and 78 mm (3.1 in.) deep, drilled in three rows from the bottom surface. In the first row, the holes are separated by 1 mm (0.04 in.); in the second row, by 2 mm (0.08 in.); and in the third row, by 4 mm (0.16 in.).

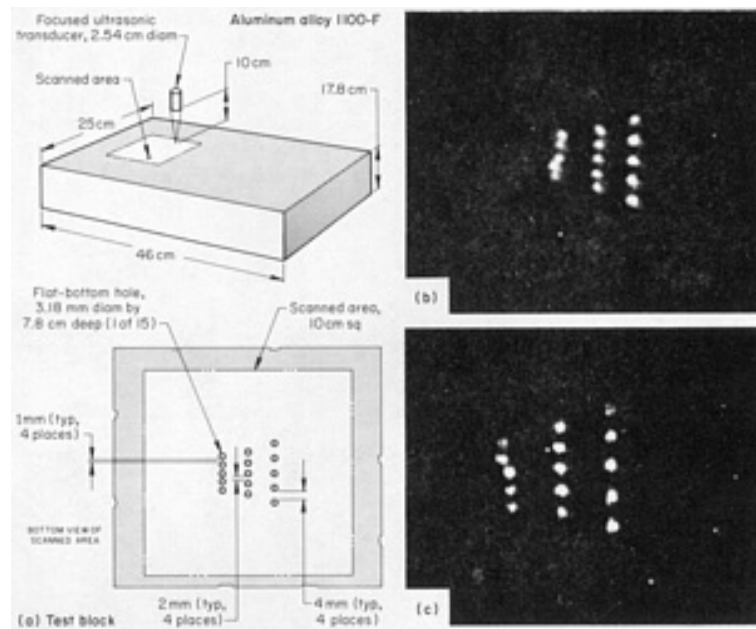

Fig. 11 Test block (a) made to measure resolution in the object plane and to locate the position of the focused ultrasonic transducer during inspection by scanning acoustical holography. (b) and (c) Reconstructed images of scanned area taken at 3.12 and 5.1 MHz, respectively

Using a focused ultrasonic transducer with a 25 mm (1 in.) diameter and a 102 mm (4 in.) focal length, two holograms were constructed of the region of the block containing the holes. When the frequency used to construct the hologram was 3.12 MHz (theoretical lateral resolution in the object plane of 2 mm, or 0.08 in., in aluminum), the holes in the left row merged while those in the middle row remained completely separate (Fig. 11b). This shows that the actual lateral resolution was slightly better than 2 mm (0.08 in.). When the frequency was increased to 5.1 MHz (theoretical lateral resolution of 1 mm, or 0.04 in.), the actual lateral resolution also increased to more than 1 mm (0.04 in.) (the holes in the left row in Fig. 11(c) are completely separate).

Acoustical Holography

Revised by B.P. Hildebrand, Failure Analysis Associates, Inc.

Interpretation of Results

The optical image that is reconstructed from an acoustical hologram is a two-dimensional presentation of a portion of a three-dimensional object. This portion consists of a subsurface layer of finite thickness oriented perpendicularly to the direction of propagation of the ultrasonic beam. The layer thickness, in turn, is a function of Δz , the depth-resolution capability of the acoustical holographic inspection system. When viewing this two-dimensional presentation, it is important to keep in mind which area is being viewed and which viewing direction (mode of ultrasonic wave propagation) was used to produce it.

When viewing ultrasonic images, the viewer should not make interpretations based on experience with optic images. The long ultrasonic waves limit the resolution so that the images produced are poor compared to those produced by visible

light waves. In addition, the coherence of the ultrasonic energy produces an effect analogous to the results obtained when viewing an object illuminated by coherent light, that is, a speckled image having highlights.

One further difficulty in the interpretation of images obtained using acoustical holographic techniques, in addition to not seeing conventional three-dimensional images, is that natural flaws are not of regular geometric configuration. The simple-shaped calibration holes in test blocks are useful in determining the sensitivity and resolution of the system, but experience with natural flaws is necessary for a correct interpretation of the reconstructed image. For this reason, it is best to obtain holograms of the flaw from two directions, but accessibility and orientation of the flaw are often restrictive. When experience is gained with different types of flaws, such as cracks, pores, and incomplete weld fusion, it is often found that they exhibit characteristic images from which comparisons can be made. Like other methods of nondestructive inspection, acoustical holography is not universal in application; often several methods must be used to reinforce its findings.

Acoustical Holography

Revised by B.P. Hildebrand, Failure Analysis Associates, Inc.

Applications

Liquid-surface and scanning systems of acoustical holography have been used commercially to inspect various types and sizes of welds and to continuously inspect sleeve-bearing stock. In addition, scanning acoustical holography has been used commercially for contouring. These applications are discussed in the following sections.

Inspection of Welds in Thin Materials. The liquid-surface equipment shown in Fig. 7 and 8 has been used to inspect welds in materials that are a few thousandths of an inch to several inches thick. For example, this equipment was used at 3 MHz to inspect spot welds between two layers of aluminum 4.11 to 4.17 mm (0.162 to 0.164 in.) thick. The reconstructed images of two welded test strips, which were used in checking machine settings for a subassembly, are shown in Fig. 12. The good welds can easily be distinguished from the poor or less satisfactory welds. The clearly defined bright spots in Fig. 12 are good welds; the smaller, less clearly defined spots are less satisfactory welds; and the completely dark spot (center arrow on left side of Fig. 12) is a poor weld.

Fig. 12 Reconstructed image of spot-welded test strips that were inspected by liquid-surface acoustical holography at 3 MHz. Arrows indicate spot-welded areas.

Another example of a weld in thin material inspected by liquid-surface acoustical holography is the weld in 1.6 mm ($\frac{1}{16}$ in.) thick titanium plate shown in Fig. 13(a). The reconstruction of the image, which was produced at 5 MHz, is shown in Fig. 13(b). The dark regions of the weld are porous; the bright regions are sound.

Fig. 13 Sine-shaped weld (a) in 1.6 mm ($\frac{1}{16}$ in.) thick titanium plate. (b) Reconstructed image of weld, produced at 5 MHz by liquid-surface acoustical holography. Arrows indicate regions containing porosity.

Inspection of Welds in Thick Materials. Most pressure vessels and pressure vessel components are thick, massive structures that contain many feet of multiple-pass welds. These welds require extensive nondestructive inspection to ensure consistent high integrity of the vessel. Scanning acoustical holography, using equipment similar to that shown in Fig. 9, has been used for the inspection of these thick welds.

An example of the use of this equipment is the evaluation of a flaw in the weld of a 152 mm (6 in.) thick steel plate. To obtain sufficient information to dimension the flaw accurately, three holograms were made, as shown in Fig. 14(a). These were made by examining the flaw with $\pm 45^\circ$ shear and 0° longitudinal sound waves. The resulting images are shown in Fig. 14(b) to (d). The data were taken at 2 MHz with a 25 mm (1 in.) diam transducer focused at the surface of the plate. A 102 mm (4 in.) focal length produced a cone of sound of approximately 60° for the longitudinal and 40° for the shear holograms.

Fig. 14 Use of scanning acoustical holography for the examination of flaws in the butt welding of a 152 mm (6 in.) thick steel plate. (a) Transducer locations above plate surface. (b) Flaw detected with $+45^\circ$ shear sound wave. (c) Flaw detected with 0° longitudinal sound wave. (d) Flaw detected with -45° shear sound wave

These three images, when properly thresholded, can be used to calculate the position and size of the flaw in three dimensions. This particular flaw was found to be 18° from vertical, with a length of 121 mm (4.76 in.) and a through wall dimension of 22.4 mm (0.88 in.). Destructive examination showed the flaw to be 114 mm (4.48 in.) in length and 13.5 mm (0.53 in.) in through wall dimension. A complete analysis of test results with ultrasonic holography is presented in Ref 4, indicating a root mean square error in estimating flaw height of ± 5.33 mm (± 0.21 in.) and length of ± 5.59 mm (± 0.22 in.).

Inspection of Sleeve-Bearing Stock. Sleeve-bearing stock for automobile engines, consisting of 0.25 mm (0.010 in.) thick leaded aluminum alloy bonded to a 2.54 mm (0.100 in.) thick steel base, has been continuously inspected by acoustical holography for unbonded regions between the two layers, using the liquid-surface equipment illustrated in Fig. 7 and 8. The stock consists of strips from 102 to 203 mm (4 to 8 in.) wide and several hundred feet long. During manufacture, the strip moves through the bonding line at a rate of approximately 152 mm/s (6 in./s).

Formerly, the strip was inspected visually for lack of bonding, as evidenced by the presence of blistered areas on the aluminum side. However, because not all the regions of poor bonding formed blisters, some regions were not physically detectable. For this reason, destructive tests using a chisel were sometimes required. With acoustical holographic equipment, unbonded regions as small as 1.6 mm ($\frac{1}{16}$ in.) in diameter are readily visible on the television monitor.

The contouring of surfaces is readily carried out with commercially available systems for scanning acoustical holography, such as those shown in Fig. 3 and 9. Contour accuracies are limited by the mechanical accuracy of the scanning equipment, but can be better than $\frac{1}{20}$ of the wavelength of ultrasound in water at 5 MHz, or about $15 \mu\text{m}$ (600 μ in.). Two examples of contour images formed by acoustical holography are shown in Fig. 15 and 16.

Fig. 15 Contour image of a spherical surface with one flat circular region (above center at right). Image was made at a frequency of 8 MHz using scanning acoustical holography. Each full fringe represents a change in elevation of $95\text{ }\mu\text{m}$ (0.00375 in.).

Fig. 16 Contour image of a Lincoln U.S. penny, made at 50 MHz using scanning acoustical holography with the coin slightly tilted with respect to the scanning plane

When a scanning acoustical holography system is used in the contouring mode, the transducer is focused on the surface to be contoured, with the central ray approximately perpendicular to the surface. The arrangement is the same as that used in forming acoustical holograms of regions lying deep within a solid material, except that a focused-image hologram is formed; that is, the scan plane is made to lie coincident with the surface to be contoured. Gating is used to eliminate the reflections from the back (far) surface of the object so that they will not interfere with the interpretation of the contours formed over the image of the front (near) surface.

Inaccessible surfaces (far surfaces) of opaque materials can also be readily contoured by moving the focal point of the transducer to the plane of the back (far) surface of the object to be contoured. In this case, the reflections from the front (near) surface are gated out.

There is no distinction between the hologram and the image in this case, because the contour lines are the hologram fringes. As in all ultrasonic inspection, a coupling medium must be used between the transducer and the surface to be examined. The object to be contoured can be immersed in water along with the scanning transducer, but this is not necessary. More often, the transducer is mounted in a water-filled cylinder that has a sliding seal in contact with the surface. The surface need not be perfectly smooth. The relatively minor loss of liquid couplant in scanning over a rough surface is replenished constantly by means of a water pump and reservoir.

A technique that has been used to achieve high resolution in optical (nonholographic) interferometry is multiple-beam interferometry (Ref 5). With this technique, contours of very smooth surfaces have been determined optically to an accuracy of better than 0.5 nm ($5\text{ }\text{\AA}$); that is, better than $\lambda/1000$, where λ is the wavelength of the light. A similar

technique can be applied to acoustical contouring by setting the reflection-signal gate to accept only the n th reflection, where the integral value of n depends on the smoothness of the surface and the amount of energy reflected at the surface. In ordinary contouring by acoustical holography, $n = 1$ and each fringe in the image represents a half-wavelength change in elevation. At 5 MHz in water, a half wavelength is $150\ \mu\text{m}$ (0.006 in.). However, if the reflection-signal gate is set to accept the tenth reflection, each fringe will represent $\frac{1}{20}$ wavelength, or about $15\ \mu\text{m}$ ($600\ \mu\text{in.}$).

Figure 17 illustrates the reflection of an ultrasonic beam from a sloping surface. As the slope angle, θ , of the surface increases in magnitude, less and less of the reflected beam is intercepted by the transducer. This limits the surface slope that can be properly contoured. This limit depends partly on the half-beam angle, ϕ , of the transducer, which in currently available systems is about 7° . A conservative rule for estimating the maximum slope angle that will be properly contoured is:

$$\theta_{\max} \approx \phi/2n \quad (\text{Eq 3})$$

Cylindrical and spherical surfaces can, in theory, be contoured to show deviations from the ideal surface by causing the focal point of the transducer to follow a scan plane shaped to the ideal surface, with the central ray kept normal to the surface.

Fig. 17 Schematic of the reflection of rays of ultrasound from a surface being contoured by scanning acoustical holography

Strain Measurement for Stress Analysis

L.D. Lineback, Measurements Group, Inc.

Introduction

EXPERIMENTAL STRESS ANALYSIS TECHNIQUES, in one form or another, can be applied at all stages in the life of load-bearing parts, members, and structures. They are used in new-product engineering, from preliminary design evaluation to production design testing; in proof and overload testing; in failure analysis, from design defect detection to redesign validation; and in materials and structural research.

Because stress is not directly measurable, the experimental analysis of engineering stresses must be based on strains, which can be readily measured by a number of techniques. With measured values of strain and a knowledge of the mechanical properties of the material from which the structure is fabricated, stresses can be calculated from the appropriate stress-strain relationship of the material.

The usual objective of stress analysis is to locate and measure the most significant strains in a part, member, or structure. These include not only the high-level strains located at stress concentrations where the product will most likely fail under load but also the lowest ones in overdesigned regions where material can be safely removed to save on costs and improve performance. Except for the simplest of designs, location of these significant strains will normally require a full-field measurement technique such as photoelasticity or brittle coatings.

Once the areas of significant strains are identified, the stress analyst generally makes one or more measurements of strain at a point to accurately determine the magnitude and direction of the principal strains. Depending on the nature of the load, type of material, and mode of failure, it may also be necessary to measure the maximum shear strain. For making these point measurements of strain, both electrical resistance strain gages and photoelastic coatings are widely used.

In addition to the kinds of strains to be measured, it is important to consider a number of other practical criteria when selecting the appropriate strain measurement technique. These generally include:

- Location of test site (laboratory or field)
- Type of loading (static, dynamic, or a combination)
- Anticipated strain range
- Required resolution and accuracy of measurement
- Operating environment (temperature, medium, and so on)
- Duration of test (from microseconds to decades)

For specialized measurements, other parameters may also require consideration.

Resistance Strain Gage Method

The bonded resistance strain gage is the most powerful and widely used strain measurement technique in the field of experimental stress analysis. Basically, the strain gage (Fig. 1) is an extremely thin, small, strain-sensitive electrical resistor bonded to a flexible backing material that, when adhesively bonded to the structure or test part, transforms surface strains into changes of electrical resistance. The resulting changes in resistance are then read out directly as strain, load, pressure, torsion, and so forth, on the appropriate instrument.

Fig. 1 Modern foil strain gage with a polyimide backing and encapsulation. About 6× actual size

Early bondable strain gages were manufactured by forming small-diameter (0.025 mm, or 0.001 in.) constantan wire into a suitable grid geometry and bonding the grid in place on a paper carrier. The active gage lengths were relatively large, typically 6 mm (0.25 in.) or longer. Today, most precision strain gages are made by etching grids into thin metal foil held in place by a compatible backing. The active gage lengths vary from 0.2 to 100 mm (0.008 to 4.000 in.). Typical gage thickness for foil gages, including backing and grid, is 0.05 mm (0.002 in.) or less.

Gage Performance. Resistance strain gages are designed to measure strain in the axial direction of the grid (Fig. 1) and to be as insensitive as possible to strains in the transverse direction. Because strain gage grids tend to yield an integrated average of the strains under them, very short gages are generally used when the strain gradient is steep. Measuring strain over as small an area as possible tends to minimize any undesirable strain integration. Longer gage lengths are intended for applications in which the mean strain over a considerable length is more representative. For example, gages with longer grids are commonly used on filament-wound composite structures to average out the strains in these nonhomogeneous materials consisting of filaments and matrix. Very long gages are used in making measurements on the surface of concrete structures having large-diameter aggregate in the cement matrix.

Gage sensitivity to strain is defined as the gage factor, GF, which is the ratio of unit change of resistance ($\Delta R/R$) to unit strain ($\Delta L/L$):

$$\frac{\Delta R/R}{\Delta L/L} = GF \quad (\text{Eq 1})$$

The gage factor is a function of the gage design, as well as the alloy used to make the gage grid, its thermomechanical history, and, to a lesser extent, the measurement temperature. Gage factors at room temperature for most typical strain gage alloys range from two to four.

Grid Geometries. Because the grid of a strain gage is designed to measure normal strains in the axial direction of the grid, various gage geometries are used during strain measurements. Because gages with single grids measure strains in a single direction, their use should be restricted to well-defined uniaxial stress states, that is, pure tension or compression. When a point measurement is required in a biaxial stress field and the directions of the principal strains are unknown or uncertain, a three-element strain gage rosette (Fig. 2a and b) should be used. With grids typically oriented at 0-45-90° or 0-60-120°, these gages enable three separate strain measurements to be made about a point in order to solve for the three unknowns (the two principal strain magnitudes and their direction). When the principal axes are known, only two independent strain measurements are required to determine the magnitudes. For these measurements, two-element "T" rosettes (Fig. 2c) are used. Rosettes are available in both stacked (grids on top of one another) and planar (grids on a single surface) geometries. Active grid lengths typically vary from 0.4 to 13 mm (0.015 to 0.500 in.) for rosettes.

Fig. 2 Typical grid geometries. (a) Three-element rosette with planar construction. (b) Three-element rosette with stacked construction. (c) Two-element T rosette. (d) Two-element pattern for measuring shear strain

Shear strains cannot be directly measured with strain gages. However, the magnitude of shear strain at a point is always equal to the difference in two orthogonal normal strains at that point with a direction that is intermediate (45°) to the orthogonal normal strains.

When the direction of the maximum shear strain is known (pure torsion, for example), the magnitude can be determined by measuring the two associated orthogonal normal strains. To ensure a proper alignment of sensing grids, gages with special shear patterns are available (Fig. 2d). For these gages, two grids are oriented at right angles to one another and at 45° angles to the longitudinal axis of the gage. When properly connected to a strain indicator, the indicated strain will be equal to the shear strain along the gage axis.

Gage Materials. The gage user has a choice of foil and backing materials to suit a wide range of performance and operating conditions. The most widely selected strain-sensing alloy for use on most materials is a copper-nickel alloy known as constantan. With a gage factor (defined in the section "Gage Performance" in this article) of about 2.1 for most grid geometries, constantan can be thermomechanically processed to minimize the effects of thermally induced resistance changes (thermal output) that occur when gages experience a change in temperature while strains are being measured. The measurement range of constantan gages is generally limited to strains of 5% or less, except for gages made from fully annealed material, which have a limit of 20%.

For elevated-temperature measurements, that is, up to 290 °C (550 °F) long-term or 400 °C (750 °F) short-term, a nickel-chromium alloy similar to Karma (Ni-20Cr-3Fe-3Al) is used for strain gage grids. With a gage factor similar to that of constantan, this alloy exhibits a higher fatigue life. The grids of gages having the greatest resistance to fatigue are made of iron-nickel-chromium-molybdenum alloy (Iso-elastic). This alloy has a high gage factor (about 3.5), but cannot be treated to minimize thermal effects. As a result, Iso-elastic gages are normally used only in dynamic applications. The strain measurement range of both Karma and Iso-elastic gages is limited to strains of 2% or less. Iso-elastic gages become very nonlinear at strains above 0.5%.

The strain gage backing serves to hold the sensing grid in place. The backing (along with the adhesive) also electrically isolates the grid from the test specimen and transfers the strains from the surface of the test part to the sensing grid. For stress analysis work, gage backings are commonly made of a tough, flexible polyimide. For extreme temperatures, that is, below -45 °C (-50 °F) or above 120 °C (250 °F), a more stable glass-reinforced epoxy phenolic is commonly used.

Gage Installation. The problem of where to install strain gages requires either a fundamental understanding of the mechanics involved or the use of photoelastic or brittle coatings to locate high and low stress regions. Photoelastic and brittle coatings will also indicate the directions of the maximum and minimum principal strains.

After the appropriate location is determined, careful installation of the gage is required in order to achieve accurate and reliable strain measurements. To accomplish this requires strict adherence to the recommended installation procedures supplied by the gage manufacturer, including the use of the proper accessory tools and supplies.

The adhesive, which must transfer the strain from the specimen surface to the gage backing, is of paramount importance in gage installation. Specially qualified cyanoacrylate adhesives are popular because of their ease of application and short, room-temperature curing cycle. However, these adhesives are degraded by time, humidity, elevated temperature, and moisture absorption. Under these conditions, an epoxy-base strain gage adhesive would be a better selection. In addition to having higher elongation capabilities, epoxies have longer cure times. Some also require elevated-temperature cures.

Care must be taken not only in selecting the best adhesive but also in choosing the correct leadwires, solders, and protective coating for the test environment. While most tests are performed in a laboratory-like environment at room temperature, by using the proper techniques and materials for bonding, wiring, and protecting strain gages, it is possible to make good strain measurements under a wide variety of difficult environmental conditions over an extended period of time. Technical data on this subject are available in a variety of forms (training programs, videotapes, publications, applications engineering assistance) from strain gage manufacturers.

Instrumentation. Because the resistance changes per unit of microstrain ($\mu\text{m/m}$) are so small (0.00024 ohms/ $\mu\text{m/m}$ for a 120-ohm gage with a gage factor of 2.000), it is usually not practical to measure the resistance directly. As a result, electrical circuits are commonly employed to convert the resistance changes into a voltage signal, which can be measured with recording instruments.

Modern strain gage instruments generally employ a Wheatstone bridge (Fig. 3) as the primary sensing circuit. A stable, high-gain dc amplifier is then used to amplify the small bridge output signal to a level suitable for driving some form of display or output device. In addition to these two basic components, a typical strain indicator (Fig. 4) includes the bridge power supply and built-in bridge completion resistors, along with balance and gain controls, provision for shunt calibration, and various convenience features.

Fig. 3 Wheatstone bridge configuration with quarter-bridge, three-wire circuit

Fig. 4 Features of a high-quality strain indicator

For a given strain, the bridge output can be increased by increasing the bridge voltage. While it is usually desirable to obtain as high an output as possible, there are limitations set by the self-heating effects, which vary with the current through the gage. The power densities that can be tolerated by the gage are strongly influenced by the specimen, which serves as a heat sink. For most practical purposes, bridge voltages are normally in the range of 1 to 15 V, with most measurements being made at voltages in the range of 2 to 5 V.

An important feature to be considered when dynamic measurements are involved is the frequency response or bandwidth of the analog output from the amplifier. Band-width specifications are normally referred to the -0.5 dB (5% loss of output) or the -3 dB (30% loss of output) point. Errors due to the frequency response of the instrumentation must be assessed by dynamic calibration with a frequency generator.

The output from the amplifier is normally in the form of an analog voltage (up to 10 Vdc), which can be fed into an appropriate indicating or recording device. For static measurements, the analog output will typically be fed to an analog-to-digital converter, with the digital signal being passed to a digital display (often built into the instrument) or to a computer. For dynamic measurements, the analog voltages are normally fed into an oscilloscope, x - y recorder, magnetic tape recorder, or recording oscillograph.

Errors. The stability and repeatability of present-day gages and instrumentation enable resolutions of strain as small as 1 $\mu\text{m/m}$. In terms of accuracy, however, measurement errors depend on a number of factors, including, primarily, gage factor uncertainties, thermal output, signal attenuation in installations with long leadwires, Wheatstone bridge nonlinearity, gage alignment errors, incomplete transmission of strain through the adhesive, sensitivity of the gage to transverse strains, and reception of noise from outside the bridge. When these sources of error are properly handled, strain measurements having inaccuracies that total 1% or less can readily be made. Inaccuracies may be higher at elevated temperatures.

Strain Measurement for Stress Analysis

L.D. Lineback, Measurements Group, Inc.

Photoelastic Coating Method

Photoelasticity is a visual full-field technique for measuring strain. When a photoelastically active material is strained and viewed under polarized light, distinct color bands (fringes) are observed (see Fig. 24a in the article "Use of Color for NDE" in this Volume). Aside from its colorful and aesthetically pleasing character, the photoelastic fringe pattern provides valuable information for the stress analyst.

Photoelasticity embraces three broad techniques: photoelastic coating, two-dimensional model analysis, and three-dimensional model analysis. Model analysis is useful at the early design stage of a product, before actual parts are made. However, the most widely used of the three techniques is the photoelastic coating method, which involves the bonding of a thin photoelastic layer to the surface of a part. When the part is loaded, the strains on its surface are transmitted to the coating. The principal-strain differences in the coating can then be determined with a reflection polariscope (Fig. 5).

Fig. 5 Reflection polariscope with a null-balance compensator being adjusted by the operator

The photoelastic coating method has many advantages over other methods of experimental stress analysis. It enables the investigator to measure surface strains in parts and structures of virtually any size, shape, or material operating under actual service conditions at or near room temperature. Additional advantages include:

- The strain field is visually displayed over the entire coated area

- The gage length is effectively zero, permitting accurate measurement of stress gradients
- Yielding is easily detected because a portion of the strain pattern remains visible after the loads are removed
- Assembly strains can be measured
- The combined effects of various load conditions can be observed and measured
- Dynamic analysis can be performed on the part or structure
- Residual stresses can be determined
- Understressed areas can be easily identified for elimination of excess material

The photoelastic coating material, usually a polymer, can be applied either by bonding prefabricated sheets to the surfaces of flat specimens or by the contour forming of photoelastic material during polymerization to complex curved surfaces (Fig. 6).

Fig. 6 Pump housing being coated with photoelastic material

Interpretation of the Photoelastic Pattern. When a photoelastic material is subjected to applied loads, changes in optical properties take place that are proportional to the strains developed; the material becomes birefringent.

Polarized light passing through a stressed material splits into two rays, each vibrating along a principal stress axis and traveling at a different speed. A relative phase shift between the two rays produces the color interference pattern, which is observed and analyzed with the polariscope. With this instrument, the plane of vibration can quickly be established to permit measurement of the principal stress direction at every point in the field. The phase shift is easily measured by optical compensation to determine the strain magnitude. In the case of a uniaxial stress condition, the stress is proportional to the product of the measured phase shift and the fringe value of the coating (microstrain per fringe). In a biaxial stress condition, the product is equal to the difference in principal strains, or the shear strain.

The photoelastic color sequence observed with increasing stress is black, yellow, red, blue-green, yellow, red, green, yellow, red, and green (see Fig. 24b in the article "Use of Color for NDE" in this Volume). A constant-color band is a contour of constant difference in principal strains. A band separating the red and green colors is defined as a fringe. The higher the fringe order, the higher the strain; the closer the bands are together, the steeper the stress gradient, indicative of a stress concentration. A uniform color area represents a constant stress area. In brief, the overall stress distribution can be easily and quickly studied by recognizing fringes, their order, and their location with respect to one another.

At any point on the band of colors, a positive identification of the fringe order is easily made by the null-balance method with a compensator. The compensator is a device that produces a calibrated phase shift equal in magnitude but opposite in sign to that occurring in the observed color pattern on the coating. When superimposed, the photoelastic effect is canceled and a black (zero) fringe is evident. This method of measurement is accurate to one-fiftieth of a fringe, or about 10 to 20 microstrain for most coatings, when coupled with a modern photoelastic data-acquisition system.

At a free boundary, where there is only one nonzero principal stress, tangent to the boundary, the maximum principal stress can be determined directly. However, because the photoelastic method of strain measurement indicates the difference in principal strains, it is sometimes necessary for the stress analyst to separate the principal strains at points other than at a free boundary. Such a situation is illustrated in Fig. 7. Separation requires that a second measurement be made at each point of interest. The most direct approach is to apply a special strain gage directly to the coating. This gage measures the sum of any two orthogonal strains at that point (an invariant). Adding the sum and difference of principal strains together and dividing the result by 2 yields the maximum principal strain at that point.

Fig. 7 Full-field capability of photoelastic coatings. (a) Measuring the effects of stress concentration near a corner of a complex part. (b) Regions near the bolts that may contain overlooked assembly stresses

A wide variety of coating materials and adhesives are available. Because the optical signal is a function of both the optical properties of the material and its thickness, selection of the proper coating should be made on the basis of anticipated strain levels. Additional considerations in coating selection include reinforcement effect, test temperature, and maximum elongation. The modulus of elasticity of coating materials ranges from 4 to 3000 MPa (0.6 to 450 ksi). Maximum allowable elongations are from 3 to 50%, or more. Testing temperatures are normally limited to the vicinity of room temperature, but the range can be extended up to about 200 °C (400 °F) under certain circumstances. Special equipment is available for casting contourable sheets from liquid materials.

Reflection polariscopes contain all the optical components necessary for photoelastic coating analysis, including a suitable light source. Stroboscopic light sources are available for making dynamic measurements. Other common options include a digital indicator, null-balance compensator (Fig. 5) camera, and telemicroscope.

Strain Measurement for Stress Analysis

L.D. Lineback, Measurements Group, Inc.

Brittle-Coating Method

For this method of strain measurement, a specialty compounded, strain-sensitive lacquer is sprayed onto the surface or part to be examined. After it has dried and the part has been loaded, the lacquer develops a series of cracks normal to the direction of the maximum tensile strain on the surface. The crack pattern (Fig. 8) provides an overall picture of the tensile strain distribution, with an indication of the strain magnitude and direction. Brittle coatings, therefore, are useful for

obtaining a quick indication of likely locations of critical stresses or stress concentrations. They are not used for detailed measurements, but for a fast, economical means of determining exact locations and orientations for subsequent strain gage installations.

Fig. 8 Cracks in a brittle coating normal to the maximum tensile strains

The brittle-coating test is particularly suitable for inaccessible areas. For example, in vehicle testing, a part to be investigated can be coated, assembled in the vehicle, and then disassembled for examination upon completion of a road test. The resultant crack pattern helps to ensure that any subsequent strain gage investigation is centered at the point of significant strains. The knowledge that measurements are taken in the correct place can reduce the test time in subsequent strain gage studies.

Digital Image Enhancement

T.N. Claytor and M.H. Jones, Los Alamos National Laboratory

Introduction

IMAGE PROCESSING AND IMAGE ENHANCEMENT have become staple methods for analyzing x-ray, tomographic, nuclear magnetic resonance (NMR), ultrasonic, thermographic, and other nondestructive evaluation (NDE) data. With image enhancement, the interpretation of complex data becomes easier for the operator. Fewer errors are made, more subtle features can be detected, and quantitative measurements are facilitated. The disadvantages of image processing are that it usually requires much more time than, for example, the visual reading of film, and it requires the operators to have basic computer skills and a knowledge of image-processing tools. This article presents an overview of image enhancement techniques with application to the needs of NDE.

Important image-processing functions for NDE applications include:

- Input device control
- Palette adjustment
- Contrast enhancement
- Scaling
- Point, and line density measurement
- A variety of filtering techniques
- Image addition and subtraction
- Trend removal (field flattening)
- Edge enhancement

In addition, there are technique-dependent processing functions, such as tomographic reconstruction or time and frequency domain processing for NMR and ultrasonic data. Numerous general image processing textbooks, handbooks, and literature overviews that address techniques used at large, in medical practice, and in industrial NDE are available (Ref 1, 2, 3, 4, 5, 6, 7, 8, 9, 10).

NDE Digital Image Enhancement Systems

The basic elements of an image-processing station are shown in Fig. 1. The station consists of:

- A computer
- Imaging software
- Mass storage
- Hard copy
- High-resolution display
- Videotape or optical disk input and output
- Other input devices
- Network interface for communication to other workstations

Data can be input from a variety of devices, it can be displayed and manipulated on a screen, the data can be archived, hard-copies can be made, and information can be exchanged with other computers. Although it is relatively easy to obtain a subset of the system shown in Fig. 1, it is difficult to find compatible hardware and software for all functions. As has been the case for the last decade, hardware and software for image-processing applications are rapidly evolving into more powerful and inexpensive products.

Fig. 1 Typical workstation configuration for use with NDE applications. A/D, analog-to-digital

The selection of a computer and software for processing is dependent mainly on the use and throughput required. Many acquisition systems, such as real-time radiographic, infrared, and ultrasonic systems, have (optional) custom image-processing capability. A high-speed computer workstation is usually desirable for multiuser use, for the use of many computationally intensive algorithms, or for the development of algorithms.

More than 50 computers have been ranked according to time required to solve a standard set of linear equations (Ref 11). From this ranking, as well as additional independent tests, the approximate time required for various image-processing functions is given in Table 1 if the code is written in C and the images are 8-bit 1024^2 . These times are very approximate because:

- The efficiency of the compiler may vary by as much as a factor of two
- Algorithms vary in coding efficiency
- Many image-processing functions are performed on integer numbers rather than in floating point form (the speed at which integer arithmetic is computed may vary greatly from the floating point value depending on the machine)

To achieve the fastest processing speeds, the computer can be augmented with an array processor or other hardware that performs a specific function rapidly. For example, 3×3 filtering can be performed on a 1024^2 by 8-bit image in 0.1 s, or fast Fourier transform (FFT) can be executed on a 1024^2 by 8-bit image in less than 10 s with the aid of an array processor. As computer processing power increases, more complicated processing functions will become practical for routine use. Digitally enhanced images are also discussed in the articles "Industrial Computed Tomography," "Thermal Inspection," and "Acoustic Microscopy" in this Volume.

Digital Image Enhancement

T.N. Claytor and M.H. Jones, Los Alamos National Laboratory

Image Capture and Acquisition System

An important part of image enhancement is the system that captures or acquires the data. In many cases, an image will be recorded on film to be digitized, or the data will come directly from an inherently digital system, such as real-time radiography, thermographic, or ultrasonic imaging system. The quality and dynamic range of the image will influence subsequent processing. It is usually desirable to have interscene dynamic ranges greater than 6 bits (64 levels). The eye has a dynamic range of about 10^{10} (photopic and scotopic combined), an interscene dynamic range of about 150, and a brightness discrimination of 2% (50 levels) (Ref 3). The schematic of a typical display system is shown in Fig. 2. Each pixel can represent a gray level or color, and if the pixel is composed of 8 bits, 256 gray shades or colors can be displayed. Because the eye has an approximate dynamic range of 150, a 256-level display is adequate for gray-level viewing. For computational purposes, for the display of color, and for the ability to fully digitize film, it is sometimes desirable to have a 12 (or more) bit pixel, which can be compressed into 8 bits for display. The display size indicated in Fig. 2 is $N \times N$; for most systems, N should be at least 512, with 1024 preferred.

Fig. 2 Concept of image display (a) and representation (b) in computer memory

Table 2 lists several types of digitizers that are currently available. Although charge-coupled device (CCD) cameras and light tables are the standard for the efficient input of medium-resolution optical data, there are other alternatives better

suiting to specific applications. The vidicons offer the highest frame rates in formats of 1024^2 and more, the line scanners have excellent resolution at moderate prices, and the micro-densitometers are the most precise with regard to photometric and geometric quantities. Most microdensitometers will digitize to 12 bits, which limits their dynamic range to about 3.6 in film density. As noted in Table 2, the standard scanning microdensitometer (row one) will take longer (up to several hours) to scan film if the film density is over 2. The laser scanners are faster (depending on the make) because of the more intense laser light source and the fact that one axis is scanned with the light beam rather than mechanically.

Table 2 Typical characteristics of image digitization devices

Type		Image quality	Pixel size or pixel number resolution	Acquisition time per 1024^2 by 8-bit image	Interscene dynamic range	Image area, mm \times mm (in. \times in.)	Face plate illumination	
							lx	ftc
Point source and detector	Microdensitometer	Excellent	5-75 μm (200 $\mu\text{in.}$ -0.0030 in.) ^(a)	≥ 15 min	≤ 4096	500 \times 500 (20 \times 20)
	Laser scanner	Excellent	35 or 75 μm (0.0014 or 0.0030 in.) ^(a)	≥ 1 min	≤ 4096	430 \times 350 (17 \times 14)

Linear CCD or photodiode arrays are good choices for film digitization and can have even better dynamic ranges than those listed in Table 2. When these devices are cooled, each 7°C (13°F) reduction in temperature reduces the root mean square noise by a factor of two. The charge-coupled device and charge injection device are capable of good dynamic range and fair resolution, but have certain artifacts (Ref 12). Again, if the devices are cooled, the noise floor is reduced, and they can be integrated for long periods to enhance the dynamic range and sensitivity. Cooled CCDs are available that rival the low light sensitivity of silicon-intensified targets (SITs), but not the frame speed.

In general, the frame rate, dynamic range, and resolution are all interrelated. The interscene dynamic range is listed as the maximum achievable for the microdensitometers and as the dynamic range that can be achieved at the given frame rate for the other devices. The faceplate illumination given for the tubes and the solid-state detectors assumes mid-level illumination (halfway between saturation and preamplifier noise) (Ref 13). This may vary among tubes and generic types by a factor of three to four (Ref 14). The interscene dynamic range will also vary greatly, but can be maximized by the proper selection of a tube such that a dynamic range of 200 can be achieved at 33 ms/field with a high resolution (>1000 lines).

The quoted resolution for the tubes is at a modulation transfer function (MTF) of 5%, which means that the contrast between a black line and a white line is only 5% at the stated resolution. This, of course, is measured at optimum illumination and at the center of the tube image field. Under other conditions, the resolution will be less. For comparison, a 1024^2 CCD camera may have an MTF of 5% at 750 lines. The lags quoted for the tubes are typical for the particular type at 3 TV fields or 50 ms. Tube cameras are primarily used in radiation environments or in specialized applications, such as high-resolution real-time radiography, in which the frame rate is higher than that achievable by current CCD designs. Charge-coupled device camera design is rapidly evolving for high-resolution scientific use and can be expected to improve with regard to real-time frame rates (Ref 12, 15).

It should be noted that a 355×432 mm (14×17 in.) film digitized at a resolution of $50\text{ }\mu\text{m}$ (0.002 in.) with 12-bit accuracy will consume a 92-Mbyte file. Just writing or reading this file to or from a hard disk could take up to 8 min (optical disks take even longer). Even with high-density optical disks and data compression, the digital storing of high-resolution radiographs represents a formidable problem.

Image Processing

Prior to image processing, it may be necessary to perform some type of preprocessing on the data. Most often, an image file will need to be converted into the workstation standard from some other type of format; for example, the files may be 8-, 16-, or 24-bit uncompressed format with a variable-length header and need to be converted to 8-bit format with no header. Typically, a problem arises when a file must be read that is in an unknown size, a compressed format, or has a limited color or nonstandard palette.

Other preprocessing functions operate on the raw data in some manner before inputting it for image processing. For example, the system should have the capability to average, filter, and acquire full frames and control the scanning parameters on the digitizer so that the noise level can be minimized. In other cases, more complicated operations are called for, such as tomographic reconstruction, synthetic aperture operations, or an FFT. Shown in Fig. 1(a) and (b) in the article "Use of Color for NDE" in this Volume are tomographs taken before and after oversampling by a factor of four and Wiener filtering of the input data set to correct for the point spread function (Ref 16). The preprocessing operation greatly increases the smoothness of the lines and reduces the artifacts.

Image Enhancement

There are three major scientific applications for image processing:

- Enhancement of an image to facilitate viewing
- Manipulation and restoration of an image
- Measurement and separation of features

These functions are listed in Table 3. Many of the functions have a dual purpose and, as will be shown, are usually combined to form other functions.

Table 3 Image-processing software algorithms useful for NDE applications

Image enhancement	Image operations	Information extraction
Contrast stretching	Scaling	Image statistics
Histogram equalization	Translation	Point, line, angle perimeter, area, measurement
Contouring	Rotating	FFT transformation, one and two dimensional
Thresholding	Registration	Correlation
Composite image building	Warping	Edge detection

Palette operations	Combining	Deblurring
Color model selection	Filtering	Motion restoration
True color representation	Thickening, thinning Noise cleaning Trend removal	Pattern recognition

Contrast Stretching and Histogram Equalization. The concept of contrast stretching is shown in Fig. 3(a). The basic operation is given by the pixel value transform:

$$\begin{aligned}
 s &= T(r) \\
 s &= T(r) = ar + b \quad \text{Linear} \\
 T(r) &= a \log(r) + b \quad \text{Logarithmic}
 \end{aligned}
 \tag{Eq 1}$$

where r is the original pixel value and s is the transformed pixel value.

Fig. 3 Concept of histogram stretching and equalization. (a) Histogram is stretched with a linear transformation. (b) Histogram is equalized such that the probability density is constant.

The linear stretch and offset method is the most commonly applied, while transforms of the nonlinear type can be used to convert film density to integrated dose or to linearize the film transfer function to account for base density. Although the manual contrast stretch is often used, a more automated contrast stretch is available with an operation known as histogram equalization. The general form is:

$$\begin{aligned}
P_r(k) &= \frac{n_k}{n} \\
s_k &= s_{\max} \sum_{j=0}^k P_r(j) \quad \text{Linear} \\
s_k &= -\frac{1}{a} \ln \left[1 - \sum_{j=0}^k P_r(j) \right] \quad \text{Exponential} \\
s_k &= s_{\max} \left(\sum_{j=0}^k P_r(j) \right)^3 \quad \text{Cube}
\end{aligned} \tag{Eq 2}$$

A simple linear equalization example is shown in Fig. 3(b). Occasionally, it may be desirable to use the cubic or logarithmic equalization. The cubic emphasizes the lower values, making the image darker, while the exponential makes the image much brighter. Other types of transfer functions are often used to remove nonlinear response in the imaging or camera system. For isolated defects, a manual stretch usually gives good results. On textured materials, however, histogram equalization often works well. An example of a linear histogram equalization of a low-contrast ultrasonic image of a bond line in an explosively bonded steel-to-aluminum plate is shown in Fig. 2 in the article "Use of Color for NDE" in this Volume.

Contouring and Thresholding. Contouring and thresholding are often combined with palette operations to show gradations in intensity or to highlight defects. Color should be used to detect gradients in intensity because the eye is sensitive to many more colors (approximately 10^4 shades) than gray levels. Thresholding can be done with a binary picture (black and white), a color scale, or a combination of gray and color. The concept of thresholding has particular application in the generation of a mask for future image-processing operations or the removal of the background. Contouring is used to change only those values between two pixel levels to a certain value. It can also be used in outlining high-definition features before further processing.

Composite Image Building. The ability to display composite images is useful in comparing the difference between images produced by different modalities, such as a radiograph and an ultrasonic or NMR image. Because image quality suffers greatly when displayed at resolutions of less than 512^2 it is imperative to have at least a 1024^2 display or to use two monitors if detailed comparisons are to be made. Figure 4 illustrates how x-ray radiographs and neutron radiographs can be displayed together and combined to enhance voids in a composite material. As shown in Fig. 4(c), the images have simply been added to enhance the detection of voids. The absorption of neutrons in the epoxy is higher than in the alumina and the reverse is true for the absorption of x-rays. However, the voids do not absorb in either case, and the contrast is therefore improved if the images are added.

Fig. 4 Voids detected in three $60 \times 60 \times 10$ mm ($2.4 \times 2.4 \times 1$ in.) alumina-filled epoxy tiles using three different imaging techniques. (a) Conventional radiography. (b) Neutron radiography. (c) Combined x-ray and neutron radiographic image. Building a composite image of both modalities indicates that there are voids in the sample. The addition of the two images enhances the voids because of the differential absorption in the matrix between the x-ray and neutron images.

Palette Control. Color can be displayed as a true color map or as a pseudocolor representation. In a pseudocolor representation, the digital data values are mapped to any color that can be produced by the combination of the red, green, and blue (RGB) values specified by a look-up table (LUT). A typical 8-bit pseudocolor system is shown in Fig. 5(a). With only an 8-bit-deep pixel as shown in Fig. 2, a type of true color is possible; however, each color is represented only by eight or fewer color levels (Fig. 5b). With 8-bits per color (as in Fig. 5c), the colors can be shaded continuously and are suitable for three-dimensional displays in which depth cueing is indicated by decreasing the luminance. Eight-bit pixels with 24-bit LUTs can produce good color scenes by adjusting the LUT to include only those colors that appear in a scene. However, the palette is then image specific.

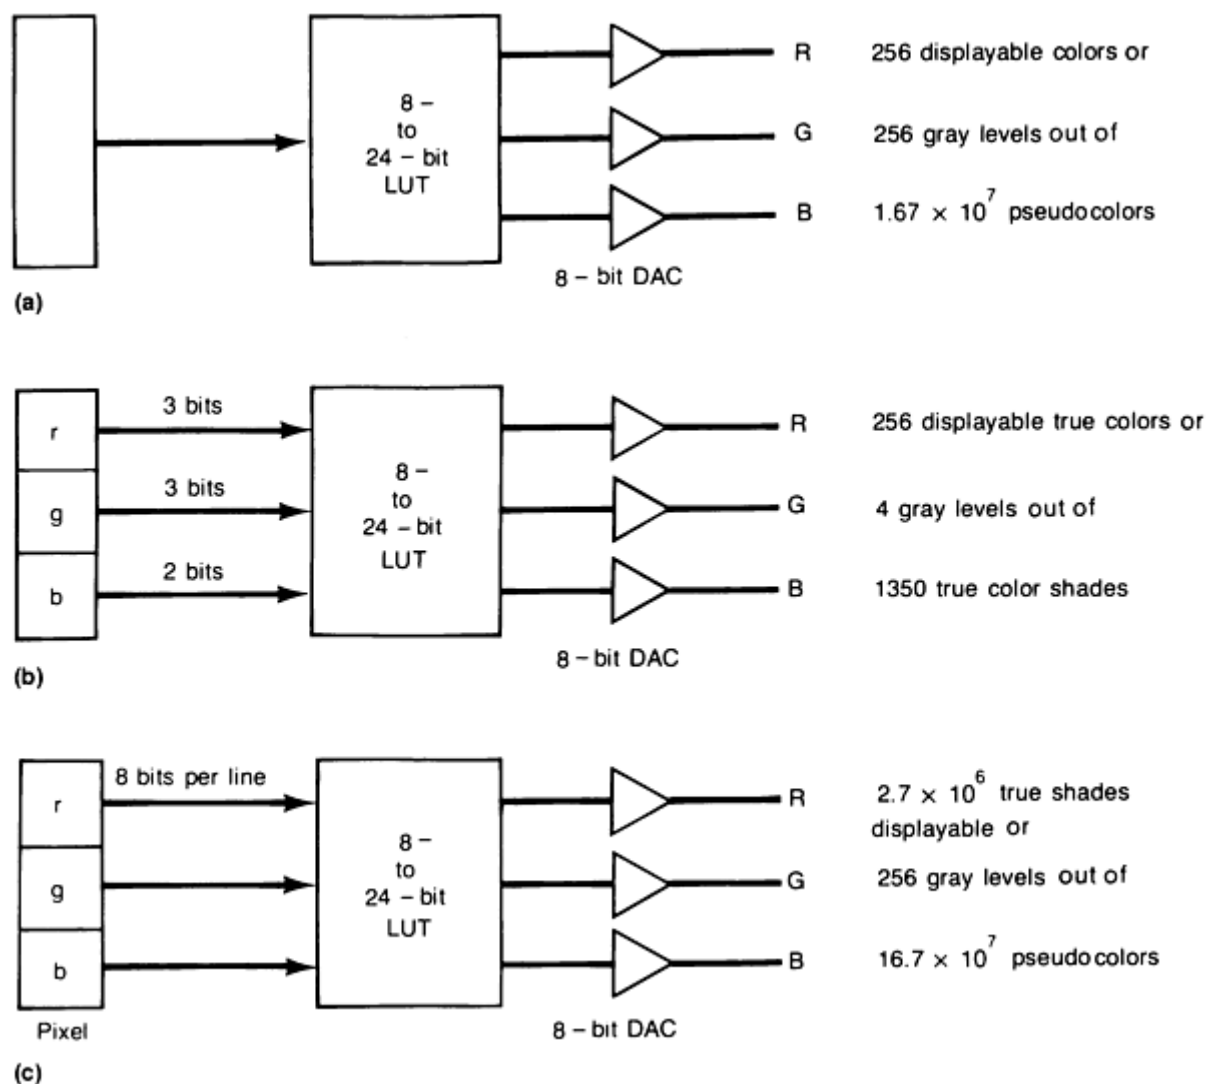

Fig. 5 Concept of a look-up table for three types of color displays. (a) 8-bit pseudocolor representation. (b) 8-bit true color map. (c) 24-bit true color map. The LUT is controlled by the palette, which specifies what color composition (R,G,B) will be assigned to one of 256 levels, as in (a). The digital-to-analog converter (DAC) converts the digital signal to RGB for input to the monitor. Shown in (b) is a way to display true color with an 8-bit pixel. Better true color can be obtained by using a 24-bit pixel, with each byte (8 bits) assigned to a specific primary color, as in (c).

Several types of pseudocolor and linear gray-scale palettes are shown in Fig. 4 in the article "Use of Color for NDE" in this Volume. The spectrum palette (or inverse spectrum) is preferred for range of color, but is not suitable for displaying rapid changes in pixel level. Other palettes, such as the complementary palettes shown in Fig. 4(d) and (e), can be used with good results on figures that have gradual changes in gray level. A typical threshold palette is shown in Fig. 4(b). All values below 192 will appear as a gray scale, while those equal to or above 192 will appear as red. The gray scale is still used to display lower-intensity data so that the operator can still detect unusual, yet not rejectable, anomalies. In contrast stretching, when further work on the image is anticipated, the palette (that is, LUT values) is altered, leaving the pixel values intact.

Color Models and the Use of Color. There are two main color models: the red, green, blue (RGB) model and the hue, saturation, luminance (HSL) model. High-resolution imaging systems use the RGB model, while the National Television Systems Committee has adopted the HSL model for broadcast television. The colors in the RGB model are simply an additive mixture of the Commission Internationale de l'Éclairage monochromatic primary colors (red = 700 nm, or 7000 Å; green = 546.1 nm, or 5461 Å; and blue = 435.8 nm, or 4358 Å). When equal intensities of these colors are combined, a nearly white light results. In the HSL model, the primaries are transformed such that the hue value represents the color (0 to 360°; red = 0, 360; green = 120; and blue = 240), the saturation is the color intensity (values 0 to 1), and

the luminance is the amount of brightness (0 to 1). If the saturation is 0 and the luminance is 1, the color will be white. The advantage of the HSL model is that a single hue can be manipulated in intensity more easily than with the RGB model.

Although both color and black-and-white images contain the same information, there are features that are much more obvious in color plots than in corresponding black-and-white plots, and vice versa. In particular, a black-and-white representation is appropriate when there is a high spatial frequency inherent in the image; in such a case, the mind-eye combination interprets this as a texture. On the other hand, color is preferred when there are a few isolated objects or low spatial frequency. This makes it easier for the image interpreter to discern small changes in image density through the use of contrast enhancement. Black-and-white images are shown in Fig. 6 and 7, and the color versions are shown in Fig. 6(c) and (d) in the article "Use of Color for NDE" in this Volume.

Fig. 6 Ultrasonic image of a hot isostatic pressed tungsten plate prepared from powder (99% dense). The black-and-white image shows small changes in density that are not easily discernible. The density changes are enhanced by the use of color, as shown in Fig. 6(c) of the article "Use of Color for NDE" in this Volume. The ring is caused by a transition from one thickness to another (the outer thickness was about 50% of the inner circle).

Fig. 7 Tungsten plate similar to the one shown in Fig. 6, except that this part was fabricated from a plate that was rolled rather than hot isostatic pressed. The black-and-white image shows a texture imparted to the material due to the inclusion of 2% porosity. The color version of the plate, Fig. 6(d) in the article "Use of Color for NDE" in this Volume, shows how difficult the texture is to interpret in a color representation using a spectrum palette.

Digital Image Enhancement

Image Operations

Listed in the second column of Table 3 are some of the more important image operations that are routinely used to manipulate images.

Geometric Processes. The scaling, rotation, translation, warping, and registration of an image are classified as geometric processes.

The scaling of an image is an important function because it is often used before images are combined. Scaling is used to magnify or shrink the images permanently to fit printer sizes or simply to view areas closely.

Rotation and translation are important mainly if two images need to be registered closely and combined or compared. The operations are described below. The scaling operation can involve interpolation, or it can merely involve a duplication of pixels. In the case of integer scaling ($\times 2$, $\times 3$), the pixels are replicated in the x and y by the integer. For noninteger scaling (such as magnification by 1.5), every other pixel is replicated. Image interpolation and noninteger scaling should be avoided unless the image is subsequently filtered or unless interpolation and scaling are the last steps in a processing chain before printing. The printer will often perform interpolation and dithering (adding a small random number to the value) to obtain an image with a smoother appearance:

$$\begin{vmatrix} u \\ v \end{vmatrix} = \begin{vmatrix} \cos \theta & -\sin \theta \\ \sin \theta & \cos \theta \end{vmatrix} \begin{vmatrix} x \\ y \end{vmatrix} \quad \text{Rotation}$$

$$\begin{matrix} ab \\ cd \end{matrix} \rightarrow \begin{matrix} aabb \\ aabb \\ ccdd \\ ccdd \end{matrix} \quad \text{Scale} \times 2$$

(Eq 3)

Warping is a nonlinear scaling process. The equation for a sixth-order warp is:

$$\begin{aligned} u &= a_1 + a_2x + a_3y + a_4xy + a_5x^2 + a_6y^2 \\ v &= b_1 + b_2x + b_3y + b_4xy + b_5x^2 + b_6y^2 \end{aligned} \quad \text{(Eq 4)}$$

This transform can be of use if an object is at an angle to the viewing plane and it is necessary to measure a feature of interest or to correct the image for the viewing angle.

Image registration can be performed by trial and error with the rotation, translation, and scaling functions. The goodness of fit can be calculated with the correlation function or by subtraction. Registration is usually a prior step to image combination.

Image Combination. Image combination operations generally include the following: AND, NAND, OR, NOR, XOR, difference, subtract, add, multiply, divide, and average. All these operations require two operands. One will be the data in the primary image, the other can be either a constant or data in a secondary image. The image combination operations are used to mask certain areas of images, to outline features, to eliminate backgrounds, to search for commonality, and/or to combine images. For example, a video of a part can be taken, edge enhanced, boosted, ANDed with 128 added to 127 and scaled and registered with a radiograph or other image, and then added to the other image.

Filtering. There are many types of spatial filters. The most useful are low pass, high pass, edge, noise, and morphological, as listed in Table 4.

Table 4 Commonly used image filters

Convolution filters	Other filters
High pass	Median
Low pass	Erosion
Horizontal edge	Dilation
Vertical edge	Unsharp mask
Laplacian	Roberts
Compass	Sobel or Prewitt
	Wiener

Many filters are classified as convolution filters. The convolution filter uses the discrete form of the two-dimensional convolution integral to compute new pixel values. In Eq 5, the image matrix is defined as $f(x,y)$, and the filter is a small 3×3 or (in general, $m \times n$) matrix called a kernel, K . In practice, the kernel is limited to a size of less than 20×20 because the FFT filtering procedure becomes faster than direct convolution for large kernels. The discrete form of the convolution integral is:

$$g(x,y) = \sum_{m=0}^{M-1} \sum_{n=0}^{N-1} f(m,n) K_{(x-m, y-n)} \quad (\text{Eq 5})$$

Because kernels are often symmetric about a 180° rotation about the center pixel, algorithms that use the correlation integral will give identical results to the convolution operation. The discrete form of the correlation integral is:

$$g(x,y) = \sum_{m=0}^{M-1} \sum_{n=0}^{N-1} f(m,n) K_{(x+m, y+n)} \quad (\text{Eq 6})$$

In this representation, one can visualize the kernel sliding over the image, with each pixel under the kernel being multiplied by the kernel value and then all values being summed to produce the new center pixel. It is customary to perform the convolution such that the initial and final image sizes are identical, with the outer row and column of the image not convolved with the kernel. Some of the most useful convolution kernels are shown in Fig. 8. Those kernels that add to 0, such as the Laplacian and the horizontal and vertical edge kernels, will remove most of the image except the edge components. The low-pass and noise reduction filters will blur the image and remove point noise, while the high-pass filters tend to sharpen the images and accentuate noise.

$$\begin{bmatrix} -1 & -1 & -1 \\ -1 & 9 & -1 \\ -1 & -1 & -1 \end{bmatrix} = 1 \quad \begin{bmatrix} 0 & -1 & 0 \\ -1 & 5 & -1 \\ 0 & -1 & 0 \end{bmatrix} = 1 \quad \frac{1}{8} \begin{bmatrix} -1 & -1 & -1 \\ -1 & 16 & -1 \\ -1 & -1 & -1 \end{bmatrix} = 1$$

High pass

$$\frac{1}{9} \begin{bmatrix} 1 & 1 & 1 \\ 1 & 1 & 1 \\ 1 & 1 & 1 \end{bmatrix} = 1 \quad \begin{bmatrix} -1 & -1 & -1 \\ 1 & 1 & 1 \\ 0 & 0 & 0 \end{bmatrix} = 0 \quad \begin{bmatrix} -1 & 1 & 0 \\ -1 & 1 & 0 \\ -1 & 1 & 0 \end{bmatrix} = 0$$

Low pass Horizontal edge Vertical edge

$$\begin{bmatrix} -1 & -1 & -1 \\ -1 & 8 & -1 \\ -1 & -1 & -1 \end{bmatrix} = 0 \quad \begin{bmatrix} 1 & 1 & 1 \\ -1 & -2 & 1 \\ -1 & -1 & 1 \end{bmatrix} = 0$$

Laplacian Compass (NE)

$$\frac{1}{9} \begin{bmatrix} 1 & 1 & 1 \\ 1 & 1 & 1 \\ 1 & 1 & 1 \end{bmatrix} = 1 \quad \frac{1}{10} \begin{bmatrix} 1 & 1 & 1 \\ 1 & 2 & 1 \\ 1 & 1 & 1 \end{bmatrix} = 1$$

Noise removal

Fig. 8 Various convolution kernels and their use

Other filters that are useful in image processing are the median, erosion, dilation, and unsharp mask filters. The median filter selects the median value in an image neighborhood (usually 3×3) and replaces the center pixel with the median value. This filter can be very effective in removing isolated pixel noise without blurring the image as severely as the low-pass filter. The effect of a low-pass and a median filter is shown on a noisy ultrasonic image of a hot-rolled plate in Fig. 3(a), (b), and (c) in the article "Use of Color for NDE" in this Volume. The erosion and dilation filters work by replacing the center pixel value in a neighborhood with the smallest or largest index in the neighborhood, respectively. They can be used to thicken or to thin boundaries. The unsharp mask filter algorithm is:

$$g(x,y) = 2 \cdot f(x,y) - L P F (f)_{xy} \quad (\text{Eq 7})$$

where LPF is the low-pass filter. The new image is the difference between the original image multiplied by a factor and the low-pass filtered image. This operation tends to enhance the contrast and to sharpen the edges slightly.

The Roberts and Sobel filters are similar types of edge detectors. The Roberts filter algorithm is:

$$g(x,y) = \{ [f(x,y) - f(x+1, y+1)]^2 + [f(x,y+1) - f(x+1, y)]^2 \}^{1/2} \quad (\text{Eq 8a})$$

This algorithm operates on a 2×2 neighborhood and will enhance high frequencies, while the Sobel filter operates with a 3×3 kernel and will produce good (but thick) outlines of images. The Sobel filter algorithm is:

$$g(x,y) = \{ \{ [f(x+1, y-1) + 2 \cdot f(x+1, y) + f(x+1, y+1)] - [f(x-1, y-1) + 2 \cdot f(x-1, y) + f(x-1, y+1)] \}^2 + \{ [f(x-1, y-1) + 2 \cdot f(x, y-1) + f(x+1, y-1)] - [f(x-1, y+1) + 2 \cdot f(x, y+1) + f(x+1, y+1)] \}^2 \}^{1/2} \quad (\text{Eq 8b})$$

A summary of the effect of various filters and edge detectors is shown in Fig. 9.

Fig. 9 Ultrasonic image of an adhesive bond ($250 \mu\text{m}$, or 0.01 in., thick) between two opaque plastic parts. (a) Unfiltered. (b) Filtered with numerous filter types (vertical edge, high pass, Laplacian, Roberts, and Sobel)

There is a class of filters that restore image quality by considering *a priori* knowledge of the noise or the degradation mechanism. An example is the inverse filter. In this case, the image has been degraded and is reestimated by the use of

the inverted degrading transfer function and a noise model to minimize the least square error. This type of filter can be useful if a transfer function model is derived for the imaging chain.

For noise cleaning, the filters listed in Table 4 and the median filter can be used. Fast Fourier transform techniques are particularly effective for the removal of periodic noise, especially filtering in the frequency domain.

Trend removal, or field flattening, is an important processing function to perform before contrast enhancement. In most cases, an x-ray film will not have a uniform density even if the part is uniform. In addition, variations in density may occur when the part is digitized with a camera. When the technique of contrast enhancement is attempted, parts of the image will saturate, and defects will be difficult to detect, as in the ceramic disk shown in Fig. 6(a) of the article "Use of Color for NDE" in this Volume. Listed below are techniques used to reduce the effect:

1. High-pass filter using an FFT
2. Low-pass filter using a large kernel or FFT, and subtracted from the original image
3. Polynomial fitted to image line and fitted curve subtracted from original

Most of these algorithms produce artifacts and are not entirely satisfactory, especially if there is a high spatial frequency superimposed on a low-frequency trend. Figure 6(b) of the article "Use of Color for NDE" in this Volume shows the results of using technique 2 (similar to unsharp masking) on a noisy image with a top-to-bottom trend.

Digital Image Enhancement

T.N. Clayton and M.H. Jones, Los Alamos National Laboratory

Information Extraction

Listed in the third column of Table 3 are image-processing functions that extract quantitative information concerning images.

Image Statistics and Measurement. The most useful image statistic needed for subsequent processing is the histogram or the probability density function. This will define the dynamic range of the image and determine subsequent processing. Also of use is the line profile and frequency analysis of the line or small area of interest. The line profile is of use when quantitative analysis needs to be performed on an image--for example, measurement of the MTF of the imaging system or the variation in pixel value across a particular defect (such as a void). The line profile can also be useful in determining the amount of trend present in an image.

Simple measurement functions that are often used are:

- Determination of the pixel value at a particular point (such as on a defect)
- Conversion of the pixel value to film density or part density
- The distance from one pixel to another in terms of pixel units or engineering units
- The angle of one line with respect to another

It is very desirable to be able to measure both the perimeter and the area of a defect. In many cases, such as a part with many voids, it may be desirable to obtain the total area of all defects above (or below) a threshold and their radius in terms of pixel values or engineering units and then to produce a histogram of the defect radii. This type of quantitative analysis is useful for material evaluation as a function of processing variables.

Fast Fourier Transform. The FFT algorithm is central to many filtering and information extraction schemes. The two-dimensional FFT is analogous to the one-dimensional FFT in that the function extracts frequency-dependent information from the waveform or image. A discrete form of the two-dimensional FFT algorithm is:

$$F(x,y) = \sum_{m=0}^{M-1} \sum_{n=0}^{N-1} f(m,n) \exp \left[-j2\pi \left(\frac{mx}{M} + \frac{ny}{N} \right) \right] \quad (\text{Eq 9})$$

Specific methods for calculating Eq 9 are given in Ref 6 and 17.

The most direct uses of the FFT and inverse FFT are as filters to eliminate periodic noise from an image. The noise may be a periodic pattern, as in the case of the filament-wound vessel shown in Fig. 10(a), or it could be 60-cycle noise. The general filter procedure is shown in Fig. 10. The image is simply transformed, edited, and inverse transformed. In Fig. 10(a), the original radiograph shows a section of a filament-wound vessel with a cut in the windings. After the transform, the signal from the filament-wound structure is seen to radiate from the center at 45° (Fig. 10b). The filament-wound structure is removed from the image by removing the frequency components of the structure as shown in Fig. 10(c). As shown in Fig. 10(c) the zero frequency component (center pixel) is left intact to restore the average gray-level value. The image is then inverse transformed to recreate the original image minus the 45° filament pattern. Figure 10(d) shows the pattern after the inverse transform; the cut section is readily apparent.

Fig. 10 General procedure used to filter an image with the FFT. (a) Original image. (b) Image transformed to the frequency domain. (c) Image edited. (d) Image inverse transformed into the filtered image

A correlation function can be used directly to detect objects or features of an image that are of interest or to align images for combination. If two images that are generated from different modalities are to be combined and a registration mark is not present, the two images can be correlated over a region of interest and moved until the correlation coefficient peaks. This is best accomplished in images having edges or texture, such as those shown in Fig. 4 and 7.

The edge detection filters described in the section "Image Operations" in this article are often used to detect or outline images; in particular, the Sobel filter works well on high-definition or noisy edges. In radiographs having noisy, fuzzy, and low-contrast edges, the Laplacian, Roberts, Sobel, and simple convolution filters will usually not produce good results. Edge followers, Hough transforms, and other *ad hoc* algorithms that depend on knowledge of the rough shape of

the curve (template matching) to be outlined work satisfactorily in most cases. These algorithms, although of some use, are usually not part of a processing package because of their specialized applications.

Advanced Functions. General formulations of image restoration functions such as motion restoration, deblurring, maximum entropy, and pattern recognition are not commonly found in general image-processing software packages, probably because of the computation required and the limited demand for these applications. These algorithms are discussed in Ref 3 (motion restoration), Ref 1 and 3 (deblurring), Ref 9 (maximum entropy), and Ref 1 and 10 (pattern recognition). The algorithms are of use in the restoration of flash radiographs or high-speed video as well as the correction of point-spread function in tomography or ultrasonics. Maximum entropy methods may be of use in the enhancement of NMR signals and other low signal-to-noise data, while pattern recognition can be of use in automating the detection of flawed, incomplete, or misassembled parts.

Image Display

A wide variety of devices and techniques are available for the display and output of the processed data.

CRT Displays. The CRT display is the standard means of output for all imaging applications because the range of colors, brightness, and dynamic range cannot be matched by any other display technology. Black-and-white monitors can have resolutions of up to 2000×1500 pixels, bandwidths of the order of 200 MHz, and a brightness of 515 cd/m^2 (150 ft-L) at a dynamic range in excess of 256. Color monitors may have 1280×1024 pixels and bandwidths of 250 MHz. High-resolution color monitors have a brightness of 85 cd/m^2 (25 ft-L) or more, with a dynamic range of 256 when viewed in dim light.

Recent advances in tube design have darkened the shadow mask by a factor of four to allow increased room illumination with no degradation in dynamic range. The only other major advance in CRT technology is the recent introduction of flat-screen tubes with resolutions up to 640×480 pixels.

The standards for video output are the RS-170, which specifies 525 lines of interlaced video at a frame rate of 30 Hz, and RS-343-A, which specifies 1023 interlaced lines also at a 30-Hz frame rate. Most modern monitors have special circuitry that enables the monitor to sync to various standards with either the sync superimposed on the green signal or as a separate input. Most high-resolution (1280×1024) imaging systems use a 483 mm (19 in.) tube operating in a noninterlaced mode at 60 to 64 Hz for the primary display.

Printers. Various color and black-and-white printers are available for hard copy. A simple method of hard copy for color and black-and-white is to photograph the CRT screen or a small (80 mm , or $3\frac{5}{32} \text{ in.}$) very flat screen directly with

an 8 × 11 in. or smaller Polaroid-type camera. The disadvantages of this method are the cost of the instant film in the large format and the small size of the image in the 4 × 5 in. format. However, the color quality of the image is excellent.

The two other types of color printers for small-system color output are ink-jet printers and thermal-transfer printers. The ink-jet printers are very inexpensive and produce vivid colors at 180 dpi on paper, but have poor contrast on transparency material. The thermal copiers are more expensive but produce high-resolution copies (300 dpi) by transferring color from a Mylar sheet onto paper or film with very good color and color density. The Polaroid cameras can reproduce all the colors seen on the screen, while the ink-jet and thermal-transfer printers will produce at least 162 colors at 150 or 90 dpi, with 2 × 2 pixel enlargement.

Table 5 lists the possible color and black-and-white hard copy output devices suitable for printing images. Impact printers and plotters are not listed, because of the limited number of colors and poor resolution. Also not listed in Table 5 are the color printers based on the Xerox process.

Table 5 Typical characteristics of color and black-and-white hard copy output devices

Device	Resolution, dpi	Image quality	
		Paper	Film
Color			
Camera	...	Excellent	Very good
Thermal transfer	300	Very good	Very good
Ink-jet	180	Good	Fair
Black and white			
Camera	...	Excellent	Very good
Laser film	300	Very good	Very good
Thermal paper	300	Good	...
Thermal transfer	300	Fair	Fair
Laser printer	300	Poor	Poor
Ink-jet	180	Poor	Very poor

There are many more black-and-white printers available than color; however, the high-quality printers are restricted to the camera type and the laser film printer. The laser film printer writes with a modulated laser directly on a special dry silver paper or film that is then developed with heat. These printers are capable of producing 64 shades of gray on paper and 128 shades on film at 300 dpi with very dense blacks. The other devices listed in Table 5 have poor resolution or low contrast.

The other black-and-white printers produce poor plots because they are binary printers (a pixel may be black or white) at 300 dpi.

To achieve a gray scale, the printer must use a 2×2 , 3×3 or other super pixel size, and this decreases the effective resolution. If a 2×2 pixel is used, the printer can print only five shades of gray at 150 dpi; if 3×3 pixels are used (100 dpi), ten shades are possible. The printers can actually produce many more shades by programming the device driver for a super pixel dithering. In this case, the program looks at a large super pixel of 5×5 , determines whether or not the pixel should be smaller, and adjusts the dot density with a dither so that, effectively, about 26 or more shades of gray are perceived with a resolution of about 100 dpi.

Videotape and Videodisk. A common use of videotape is to input TV frames from a dynamic test to the image-processing system. For example, a high-speed video can be made of a pressure vessel as it bursts. Later, the sequential frames are captured and enhanced to determine the shape of the initiation crack or the speed of crack growth. Conversely, radiographs can be made periodically during the slow evolution of a part under the influence of some external variable (for example, void coalescence in ceramics as a function of temperature). The radiographs are then digitized and interpolated to form a time-compressed video.

Videodisks can be made in a write once read many format with relatively inexpensive machines. Videodisks offer better resolution and more convenient frame access than videotape. Another alternative for the display of dynamic data is to use the hard disk in the imaging workstation. Hard disk transfer rates (300 kbytes/s) allow small (200×200) movies to be shown on a workstation screen for tens of seconds (depends on disk size) at seven frames per second. Ultimately, it will be possible to expand compressed data quickly enough so that it can be read off a hard disk or a removable digital optical disk in near real time for significant durations.

The processing of tape can be tedious because of the amount of data required for a few seconds of video and also because of the limited resolution. However, the techniques of video data display are a very powerful enhancement tool because of the attraction of the eye to changing features.

Pseudo Three-Dimensional Images. All discussion of output data display has been in terms of a flat two-dimensional representation. This is the display of preference for processing because the algorithms are available or easily coded. However, depending on the data and the method of acquisition, other types of displays may be more appropriate. Shown in Fig. 10(a) and (b) in the article "Use of Color for NDE" in this Volume are two ways to present two-dimensional data in three dimensions. In Fig. 10(a), a two-dimensional ultrasonic microscopy image of a circuit board is shown with two defective metallic conductor pads (Ref 18). The image lines are drawn, as in the terrain-mapping method, with high values elevated with respect to low values and with a hidden line algorithm. Another way to present two-dimensional image data is shown in Fig. 10(b). In this case, the two-dimensional ultrasonic data were taken from a C-scan of a filament-wound sphere with Teflon shims imbedded in the matrix (Ref 19). Presenting the two-dimensional data in this manner results in a realistic display and facilitates interpretation.

Tomographic, ultrasonic, and NMR data sets may consist of many two-dimensional images that can be stacked to yield a picture of a true three-dimensional object. There are two ways to represent this three-dimensional data. In the first method, the data are modeled as a geometric solid or surface; in the second method, the data are displayed as raw data, or voxels (volume elements). The first method is used in solids-modeling workstations for design engineering. It can also be used to image NDE data, especially if the number of modeled elements is very large (10^5 or more) or has many surfaces. Figure 11 shows a three-dimensional reconstruction of a bundle of bent fuel rods after a reactor accident test. The image was constructed of 250 individual 128×128 pixel tomograms. A type of surface modeling that treats surfaces as polygons was used to model the rods. An inspection of the original tomograms shows that it is impossible to quickly grasp the shape of the bent rods from simple two-dimensional plots (Ref 20). Another three-dimensional reconstruction of this failed assembly can be found in Fig. 9 in the article "Use of Color for NDE" in this Volume.

Fig. 11 Three-dimensional perspective plot representation of a bundle of failed, bent fuel rods. The representation was reconstructed from three-dimensional data sets obtained from a series of 250 individual 128×128 pixel tomographic slices of the rod bundle.

Figure 8 in the article "Use of Color for NDE" shows a tomogram of a turbine blade that was displayed in terms of voxel imaging (also known as volume rendering), rather than modeling the surfaces by polygons or other shapes. Volume elements are created from the raw data, and these voxels are then projected to a view surface to produce an image. The raw data are not actually displayed. Figure 8 also demonstrates how the surfaces can be made transparent and the lighting model adjusted for a realistic effect. Graphics accelerators are available so that the images shown in Fig. 8 can be rotated, lighting sources adjusted, and textures added in almost real time (see Fig. 7 of the article "Use of Color for NDE" in this Volume). Three-dimensional image processing is in its infancy, but many medical and NDE applications are envisioned (Ref 21).

Acoustic Microscopy

Lawrence W. Kessler, Sonoscan, Inc.

Introduction

ACOUSTIC MICROSCOPY is the general term applied to high-resolution, high-frequency ultrasonic inspection techniques that produce images of features beneath the surface of a sample. Because ultrasonic energy requires continuity of materials to propagate, internal defects such as voids, inclusions, delaminations, and cracks interfere with the transmission and/or reflection of ultrasound signals. Compared to conventional ultrasound imaging techniques, which operate in the 1 to 10 MHz frequency range, acoustic microscopes operate up to and beyond 1 GHz, where the wavelength is very short and the resolution correspondingly high. In the early stages of acoustic microscopy development, it was envisioned that the highest frequencies would dominate the applications. However, because of the high-attenuation properties of materials, the lower frequency range of 10 to 100 MHz is extensively used. Acoustic microscopy is recognized as a valuable tool for nondestructive inspection and materials characterization. Acoustic microscopy comprises three different methods:

- Scanning laser acoustic microscopy (SLAM), which was first discussed in the literature in 1970 (Ref 1)
- C-mode scanning acoustic microscopy (C-SAM), which is the improved version of the C-scan instrumentation (Ref 2)
- Scanning acoustic microscopy (SAM), which was first discussed in the literature in 1974 (Ref 3)

Each of these methods has a specific range of utility, and most often the methods are noncompetitive with regard to applications. That is, only one method will be best suited to a particular inspection problem.

Acoustic microscopes are practical tools that have emerged from the laboratory to find useful applications within industry. They can be applied to a broad range of problems that previously had no solutions, and they have been especially useful in solving problems with new high-technology materials and components not previously available. The three acoustic microscope types can be as different from each other as are microradiography and electron microscopy. This discussion should provide the potential user with an awareness of the techniques and their distinctions in order to maximize the opportunities for the successful use of acoustic microscopy.

Acoustic Microscopy

Lawrence W. Kessler, Sonoscan, Inc.

Fundamentals of Acoustic Microscopy Methods

As a general comparison between the methods, the scanning laser acoustic microscope is primarily a transmission mode instrument that creates true real-time images of a sample throughout its entire thickness (reflection mode is sometimes employed). In operation, ultrasound is introduced to the bottom surface of the sample by a piezoelectric transducer, and the transmitted wave is detected on the top side by a rapidly scanning laser beam.

The other two types of microscopes are primarily reflection mode instruments that use a transducer with an acoustic lens to focus the wave at or below the sample surface. The transducer is mechanically translated (scanned) across the sample in a raster fashion to create the image. The C-mode scanning acoustic microscope can image several millimeters or more into most samples and is ideal for analyzing at a specific depth. Because of a very large top surface reflection from the sample, this type of microscope is not effective in the zone immediately below the surface unless the Rayleigh-wave mode to scan near-surface regions is used along with wide-aperture transducers. The scanning acoustic microscope uses this Rayleigh wave mode and is designed for very high resolution images of the surface and near-surface regions of a sample. Penetration depth is intrinsically limited, however, to only one wavelength of sound because of the geometry of the lens. For example, at 1 GHz, the penetration limit is about 1 μm (40 $\mu\text{in.}$). The C-mode scanning acoustic microscope is designed for moderate penetration into a sample, and transmission mode imaging is sometimes employed. This instrument uses a pulse-echo transducer, and the specific depth of view can be electronically gated. More detailed discussions of each acoustic microscopy technique follow.

SLAM Operating Principles

A collimated plane wave of continuous-wave (CW) ultrasound at frequencies up to several hundred megahertz is produced by a piezoelectric transducer located beneath the sample, as illustrated in Fig. 1. Because this ultrasound cannot travel through air (making it an excellent tool for crack, void, and disbond detection), a fluid couplant is used to bring the ultrasound to the sample. Distilled water, spectrophotometric-grade alcohol, or other more inert fluids can be used, depending on user concerns for sample contamination. When the ultrasound travels through the sample, the wave is affected by the homogeneity of the material. Wherever there are anomalies, the ultrasound is differentially attenuated, and the resulting image reveals characteristic light and dark features, which correspond to the localized acoustic properties of the sample. Multiple views can be made to determine the specific depth of a defect, as is performed by stereoscopy (Ref 4).

Fig. 1 Simplified view of the methods for producing through transmission and noncollinear reflection mode acoustic images with the scanning laser acoustic microscope

A laser beam is used as an ultrasound detector by means of sensing the infinitesimal displacements (rippling) at the surface of the part created by the ultrasound. In typical samples that do not have polished, optically reflective surfaces, a mirrored plastic block, or coverslip, is placed in close proximity to the surface and is acoustically coupled with fluid. The laser is focused onto the bottom surface of the coverslip, which has an acoustic pattern that corresponds to the sample surface. By rapid sweeping of the laser beam, the scanning laser acoustic microscope images are produced in real time (that is, 30 pictures per second) and are displayed on a high-resolution video monitor. In contrast to other less accurate uses of the term real time in industry today, the scanning laser acoustic microscope can be used to observe events as they occur--for example, a crack propagating under an applied stress. The images produced by SLAM are shadowgraph mode images of structure throughout the thickness of the sample. This provides the distinct advantage of simultaneous viewing of the entire thickness of the sample, as in x-ray radiography. In situations where it is necessary to focus on one specific plane, holographic reconstruction of the SLAM data can be employed (Ref 5, 6).

Figure 2 shows a system block diagram for the scanning laser acoustic microscope. In addition to an acoustic image on a CRT, an optical image is produced by means of the direct scanned laser illumination of the sample surface. For this mode, the reflective coating on the coverslip is made semi-transparent. The optical image serves as a reference view of the sample for the operator to consult for landmark information, artifacts, and positioning of the sample to known areas. The SLAM acoustic images also provide useful and easily interpreted quantitative data about the sample. For example, the brightness of the image corresponds to the acoustic transmission level. By removing the sample and restoring the image brightness level with a calibrated electrical attenuator placed between the transducer and its electrical driver, precise insertion loss data can be obtained (Ref 7, 8). With the acoustic interference mode, the velocity of sound can be measured in each area of the sample (Ref 9, 10). When these data are used to determine regionally localized acoustic attenuation loss, modulus of elasticity, and so on, the elastic microstructure can be well characterized.

Fig. 2 Schematic showing principal components of a scanning laser acoustic microscope. The unit employs a plane wave piezoelectric transducer to generate the ultrasound and a focused laser beam as a point source detector of the ultrasonic signal. Acoustic images are produced at a rate of 30 images per second.

The simplest geometries for SLAM imaging are flat plates or disks. However, with proper fixturing, complex shapes and large samples can also be accommodated. For example, tiny hybrid electronic components, large (254 × 254 mm, or 10 × 10 in.) metal plates, aircraft turbine blades and ceramic engine cylinder liner tubes have been routinely examined by SLAM.

C-SAM Operating Principles

The C-mode scanning acoustic microscope is primarily a pulse-echo (reflection-type) microscope that generates images by mechanically scanning a transducer in a raster pattern over the sample. A focused spot of ultrasound is generated by an acoustic lens assembly at frequencies typically ranging from 10 to 100 MHz. A schematic diagram is shown in Fig. 3.

Fig. 3 Schematic of the C-mode scanning acoustic microscope. This instrument incorporates a reflection, pulse-echo technique that employs a focused transducer lens to generate and receive the ultrasound signals beneath the surface of the sample.

The ultrasound is brought to the sample by a coupling medium, usually water or an inert fluid. The angle of the rays from the lens is generally kept small so that the incident ultrasound does not exceed the critical angle of refraction between the fluid coupling and the solid sample. Note that the focal distance into the sample is shortened considerably by the liquid-solid refraction. The transducer alternately acts as sender and receiver, being electronically switched between the transmit and receive modes. A very short acoustic pulse enters the sample, and return echoes are produced at the sample surface and at specific interfaces within the part. The return times are a function of the distance from the interface to the transducer. An oscilloscope display of the echo pattern, known as an A-scan, clearly shows these levels and their time-distance relationships from the sample surface, as illustrated in Fig. 4. This provides a basis for investigating anomalies at specific levels within a part. An electronic gate selects information from a specific level to be imaged while it excludes all other echoes. The gated echo brightness modulates a CRT that is synchronized with the transducer position.

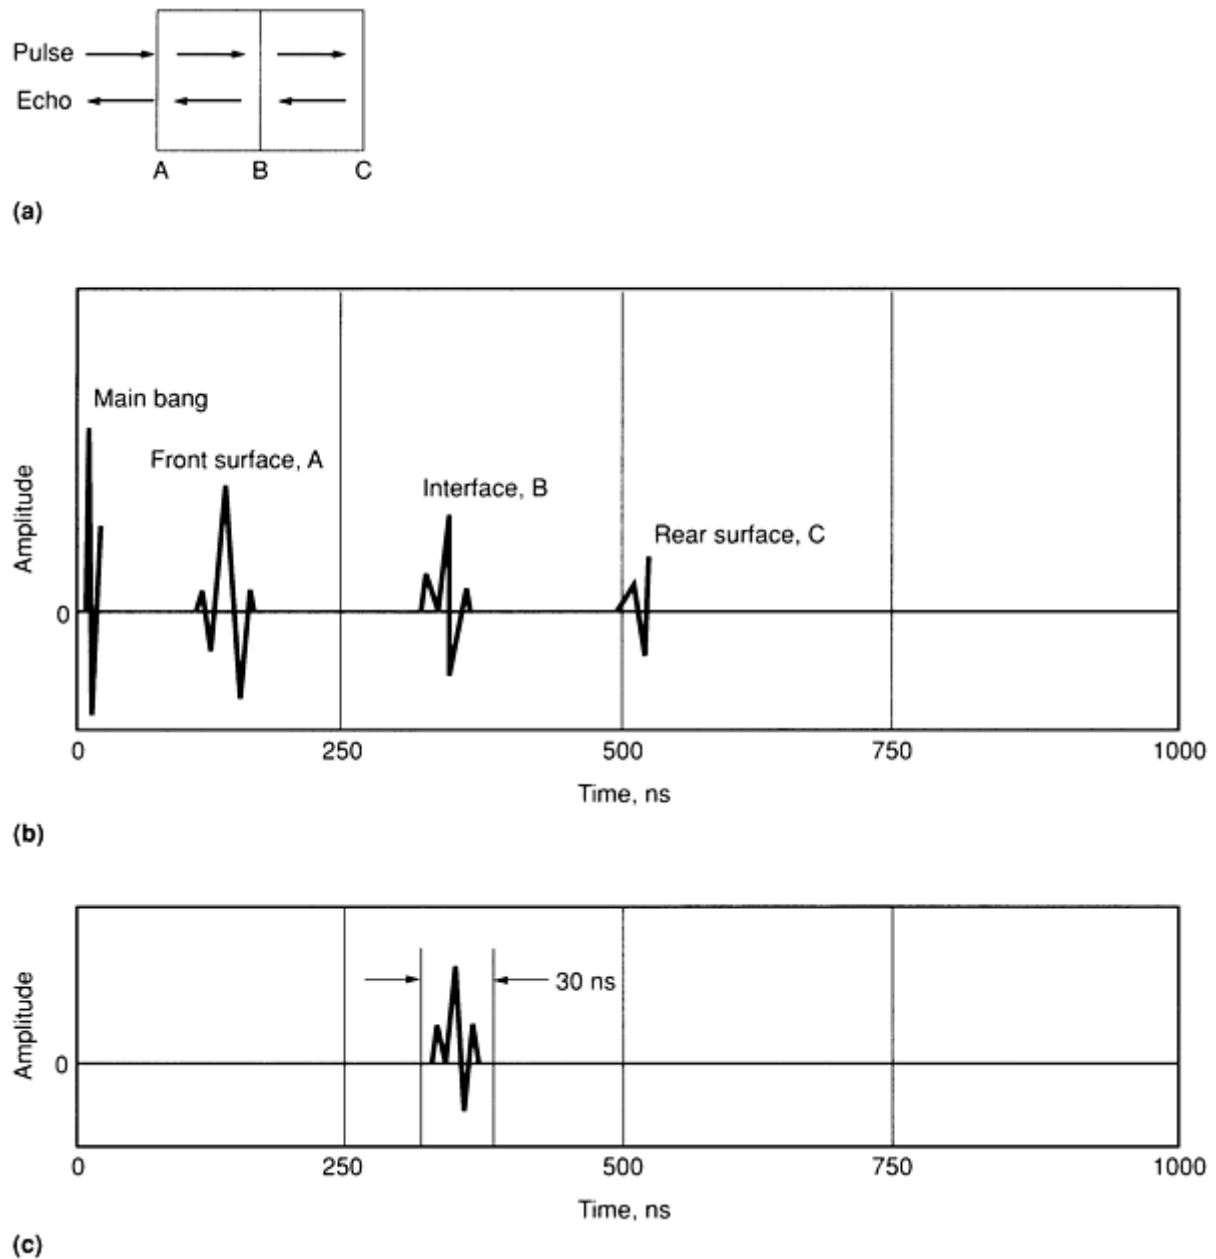

Fig. 4 Signal/source interfaces and A-scan displays for typical sample. (a) Simplified diagram showing pulses of ultrasound being reflected at three interfaces: front surface, A; material interface, B; and rear interface, C. Main bang is the background electrical noise produced by transducer excitation. (b) Plot of amplitude versus time as transducer is switched between transmit and receive modes at each interface during a time span of under 1 μ s. (c) Signal at interface B gated for a duration of 30 ns

Compared to older conventional C-scan instruments, which produce a black/white output on thermal paper when a signal exceeds an operator-selected threshold, the output of the C-mode scanning acoustic microscope is displayed in full gray scale, in which the gray level is proportional to the amplitude of the interface signal (gray-scale digitization is discussed in the article "Machine Vision and Robotic Evaluation" in this Volume). The gray scale can be converted into false color, and as shown in Fig. 5, the images can also be color coded with echo polarity information (Ref 11). That is, positive echoes, which arise from reflection from a higher-impedance interface, are displayed in a gray scale having one color scheme, while negative echoes, from reflections off of lower-impedance interfaces are displayed in a different color scheme. This allows quantitative determination of the nature of the interface within the sample. For example, the echo amplitude from a plastic-ceramic boundary is very similar to that from a plastic-airgap boundary, except that the echoes are 180° out of phase. Thus, to determine whether or not an epoxy is bonded to a ceramic, echo amplitude analysis alone is not sufficient. The color-coded enhanced C-mode scanning acoustic microscope is further differentiated from conventional C-scan equipment by the speed of the scan. Here, the transducer is positioned by a very fast mechanical

scanner that produces images in tens of seconds instead of tens of minutes for typical scan areas to cover the size of an integrated circuit.

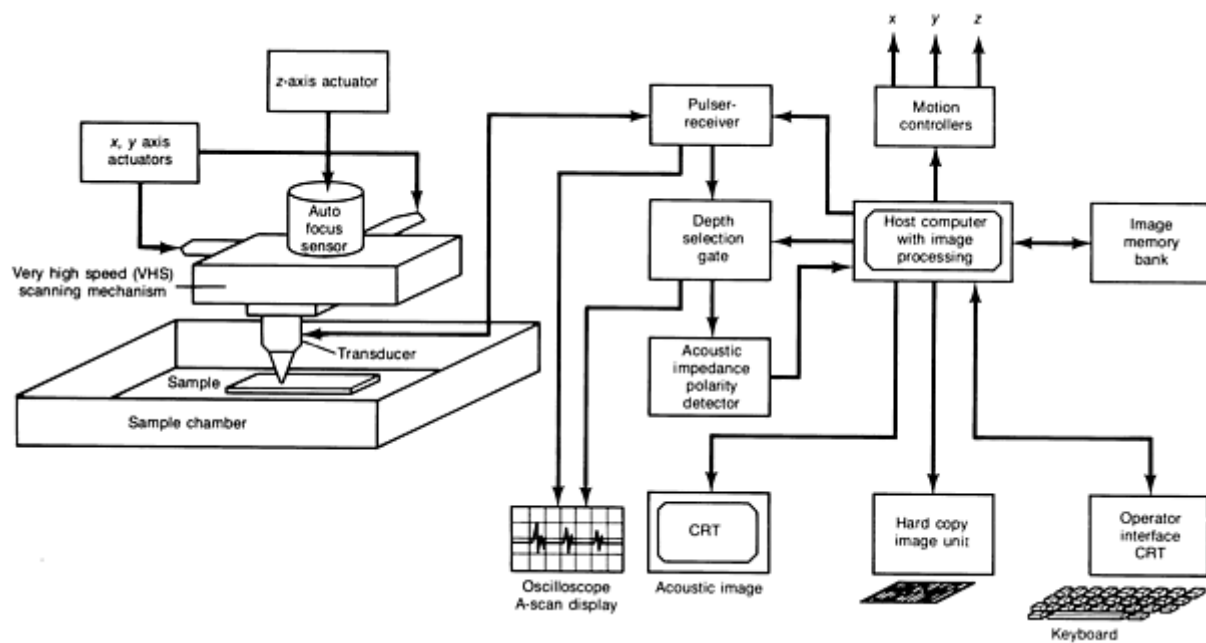

Fig. 5 Schematic and block diagram of the C-mode scanning acoustic microscope. The instrument employs a very high speed mechanical scanner and an acoustic impedance polarity detector to produce high-resolution C-scan images.

With regard to the depth zone within a sample that is accessible by C-SAM techniques, it is well known that the large echo from a liquid/solid interface (the top surface of the sample) masks the small echoes that may occur near the surface within the solid material. This characteristic is known as the dead zone, and its size is usually of the order of a few wavelengths of sound or more. Far below the surface, the maximum depth of penetration is determined by the attenuation losses in the sample and by the geometric refraction of the acoustic rays, which shorten the lens focus by the solid material. Therefore, depending on the depth of interest within a sample, a proper transducer and lens must be used for optimum results.

SAM Operating Principles

The scanning acoustic microscope is primarily a reflection-type microscope that generates very high resolution images of surface and near-surface features of a sample by mechanically scanning a transducer in a raster pattern over the sample (Fig. 6 and 7). In the normal mode, an image is generated from echo amplitude data over an x,y scanned field-of-view. As with SLAM, a transmission interference mode can be configured for velocity of sound measurements. In contrast to C-SAM, a more highly focused spot of ultrasound is generated by a very wide angle acoustic lens assembly at frequencies typically ranging from 100 to 2000 MHz. The angle of the sound rays is well beyond the critical cutoff angle, so that there is essentially no wave propagation into the material. There is a Rayleigh (surface) wave at the interface and an evanescent wave that reaches to about one wavelength depth below the surface. As in the other techniques, the ultrasound is brought to the sample by a coupling medium, usually water or an inert fluid. The transducer alternately acts as sender and receiver, being electronically switched between the transmit and receive modes. However, instead of a short pulse of acoustic energy, a long pulse of gated radio-frequency (RF) energy is used. No range gating is possible, as in C-SAM, because of the basic design concept of the SAM system. The returned acoustic signal level is determined by the elastic properties of the material at the near-surface zone. The returned signal level modulates a CRT, which is synchronized with the transducer position. In this way, images are produced in a raster scan on the CRT. As with C-SAM, complete images are produced in about 10 s.

Fig. 6 Schematic of the scanning acoustic microscope lens used for interrogating the surface zone of a sample

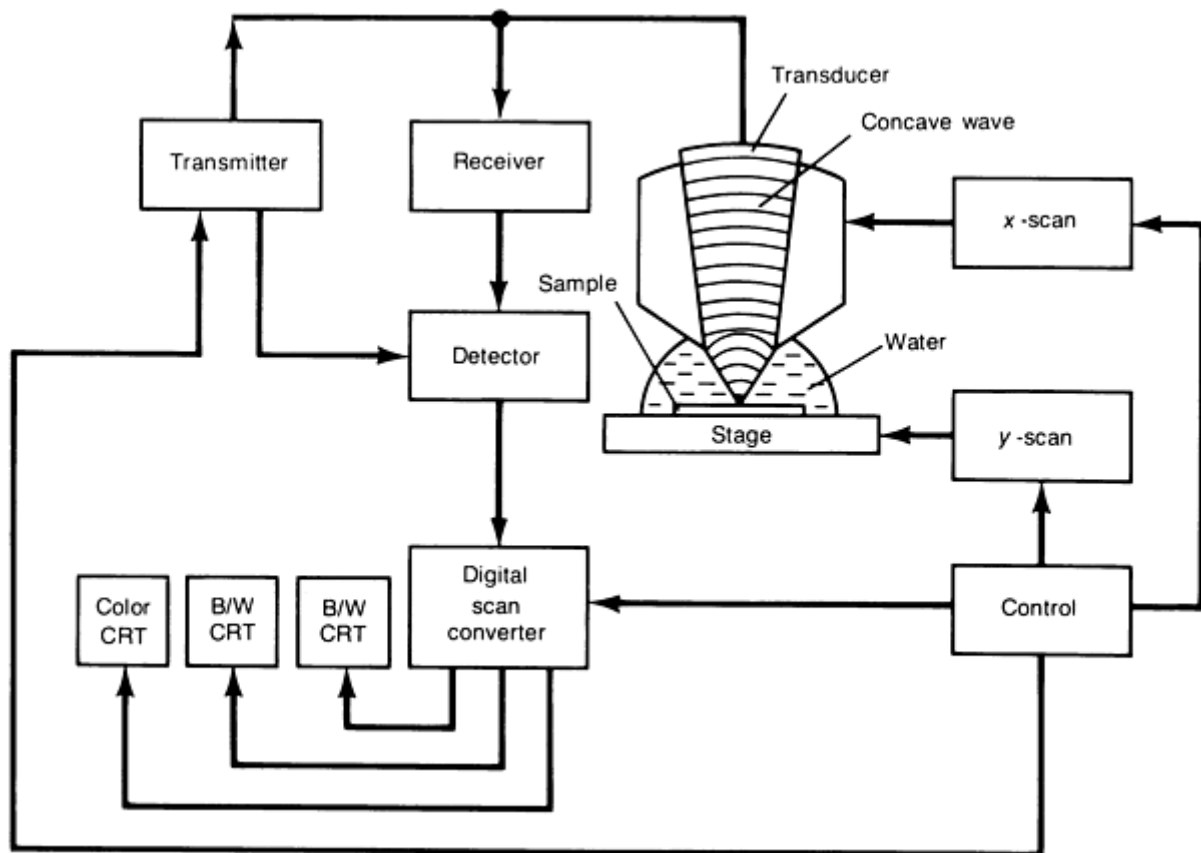

Fig. 7 Block diagram of a reflective-type SAM system that uses mechanical scanning of a highly focused transducer to investigate the surface zone of a sample at high magnification

With the SAM technique operating at very high frequencies, it is possible to achieve resolution approaching that of a conventional optical microscope. This technique is employed in much the same way as an optical microscope, with the important exception that the information obtained relates to the elastic properties of the material. Even higher resolution than an optical microscope can be obtained by lowering the temperature of operation to near 0 K and using liquid helium

as a coupling fluid. The wavelength in the liquid helium is very short compared to that of water, and submicron resolution can be obtained (Ref 12).

The SAM technique has also been found to be useful for characterizing the elastic properties of a sample over a microscopic-size area, which is determined by the focal-spot size of the transducer. In this method, the reflected signal level is plotted as a function of the distance between the sample and the lens. Because of the leaky surface waves generated by mode conversion at the liquid/solid interface as the sample is defocused toward the lens, an interference signal is produced between the mode converted waves and the direct interface reflection. The curve obtained is known as the $V(z)$ curve; by analyzing the periodicity of the curve, the surface wave velocity can be determined. Furthermore, defocusing the lens enhances the contrast of surface features that do not otherwise appear in the acoustic image (Ref 13, 14). In addition, by using a cylindrical lens instead of a spherical lens, the anisotropy of materials can be uniquely characterized (Ref 15).

Comparison of Methods to Optimize Use of Techniques

Figure 8 illustrates the zones of application for all three types of acoustic microscopy techniques. The differences are substantial with regard to the potential for visualizing features within a sample, and they should be carefully weighed before a particular method is selected. Table 1 lists some of the major advantages and benefits of the techniques. However, generalizations are sometimes difficult to make. Proposed or laboratory-demonstrated solutions to some of the limitations of each technique may already exist. Table 1 was prepared on the basis of instrumentation and techniques that are commercially available and therefore should be used only as a general guide.

Table 1 Comparison of industrial acoustic microscopy techniques

Parameter	SLAM	C-SAM	SAM
General description	Utilizes CW, plane wave ultrasonic illumination of sample and scanning focused laser beam detection of ultrasound; simultaneous optical images and acoustic images are produced. SLAM produces images in real time, which is the fastest of all acoustic microscopy techniques.	High-resolution focused-beam C-scan ^(a) . Utilizes pulse-echo mode and has full gray-scale image output. Images are produced by mechanically scanning the transducer over the sample area.	Utilizes very highly focused acoustic lenses to image exterior surfaces by means of surface acoustic wave generation. Images are produced by mechanically scanning the transducer over the sample area. SAM produces the highest resolution of all acoustic microscopy techniques.
Primary use	Nondestructive testing and materials characterization	Nondestructive testing and materials characterization	Materials characterization and research
Frequency range	10-500 MHz	10-100 MHz	100 MHz-2 GHz
Resolution	Resolution limited to the wavelength of ultrasound within the sample material	Resolution limited to the wavelength of ultrasound within the sample material, multiplied by a factor, typically 2-10, due to the lens design	Resolution limited to the wavelength of ultrasound within the coupling fluid at the surface of the sample
Imaging mode	Through transmission (primarily); off-axis reflection; orthoscopic view of sample	Reflection (primarily); orthoscopic view of sample	Reflection (only); orthoscopic view of sample
Image information	Image produced is an acoustic shadowgraph representing the entire thickness of the sample.	Image is produced at any selected depth within the sample, but is affected by wave propagation through all the levels prior to the focus location.	Image is produced only at the sample surface, and the depth of the information extends into the material a distance of one

			wavelength of sound.
Ultrasound mode	Continuous-wave and frequency-modulated ultrasound waves	Short pulses of ultrasound, less than a few cycles of RF in duration	Gated RF (or tone burst) containing many cycles (10-100) of RF at frequency selected
Ultrasound signal timing	Not applicable due to CW	Echoes are spread out in time, and one is selected and electronically gated for desired image depth within sample.	Gated at the surface of the sample where virtually all the ultrasound is reflected. There are no subsurface echoes to select.
Transducer type	Plane wave transducer for sample illumination and focused laser beam for detection	Focused transducer used for transmit and receive mode. The angle of the rays is less than the critical angles between the coupling fluid and the sample. This is known as a low-numerical-aperture transducer.	Focused transducer in which the geometric angle of the rays is much greater than the critical angles in order to excite surface modes. This is known as a high-numerical-aperture transducer.
Image outputs	Amplitude mode: Records level of ultrasound transmission at each x,y coordinate of the scan Interference mode: Records velocity of sound variations within sample over the field-of-view at each frequency Frequency scan mode: Similar to amplitude mode except that the insonification frequency is swept over a range to eliminate speckle and other artifacts of coherent imaging Optical mode: Laser scanned optical image produced in synchrony with the acoustic images	C-mode: Records echo amplitudes at each x,y coordinate of the scan; image output on CRT A-scan: Oscilloscope display of the echo pattern as a function of time (distance into sample) at each x,y coordinate. This can be used to measure the depth of a feature or the velocity of sound in the material. The A-scan is used to determine the setting of the echo gate, which is critical to the composition and interpretation of the images.	Normal mode: Records reflected energy from surface at each x,y position. Image output on CRT. $V(z)$, or acoustic material signature graph, records the change in reflected signal level at any x,y coordinate as the z position is varied (Ref 12, 13, 14). This will characterize the material by means of its surface acoustic wave velocity. Interference mode: Records velocity of sound variations within sample over the field-of-view at each frequency
Depth of penetration	Penetration is limited by acoustic attenuation characteristic of sample.	In addition to attenuation by the sample, penetration is limited by focal length of lens and geometric refraction of the rays, which causes shortening of the focus position below the surface. There is also a dead zone just under the surface due to the large-amplitude front-surface echo, which masks smaller signals occurring immediately thereafter. This can be rectified with a high-numerical-aperture transducer.	Limited to a distance of one wavelength of sound below the surface. There is essentially no wave propagation into the sample.
Imaging speed	True real-time imaging: 30 frames/s; fastest of all acoustic microscopes	10 s to 30 min per frame; varies greatly among manufacturers	10 to 20 s/frame
New developments	Holographic reconstruction of each plane through the depth of the sample (Ref 5, 6)	Acoustic impedance polarity detector to characterize the physical properties of the echo producing interfaces (Ref 11)	Low-temperature liquid helium stages for extremely high resolution images (Ref 15)

- (a) C-scan produces ultrasonic images by mechanically translating a pulsed transducer in an x,y plane above a sample while recording the echo amplitude within a preset electronic time gate. The transducer may be planar or focused. The frequencies of operation are typically 1-10 MHz, and the data are usually displayed as a binary brightness level on a hard copy output unit, such as thermal paper. A threshold level selected by the operator determines the transition between what amplitude of echo is displayed as a bright or dark image print.

Acoustic Microscopy Applications*

It is difficult to document concisely the very broad range of applications for acoustic microscopy, but a few generalizations can be made that follow the examples of conventional ultrasonic nondestructive testing (see the articles "Ultrasonic Inspection" and "Adhesive-Bonded Joints" in this Volume). Acoustic microscopy is compatible with most metals, ceramics, glasses, polymers, and composites (made from combinations of the above materials). The compatibility of a material is ultimately limited by ultrasound attenuation caused by scattering, absorption, or internal reflection. In metals, the grain structure causes scattering losses; and in ceramics, the porosity may cause losses. The magnitude of these effects generally increases with ultrasound frequency, and the dependence is monotonic.

Figure 9 shows a general guide to acoustic microscopy applications with respect to imaging. The quantitative aspects have not yet found widespread industrial acceptance, although they are extremely important and form the basis for materials characterization. The techniques of SLAM, C-SAM, and SAM all produce quantitative data in addition to images. Acoustic microscopy methods are compared below with a typical C-scan ultrasound method in terms of frequency employed:

Method	Frequency range, MHz
C-scan ultrasound	1-10
Acoustic microscopy	
C-SAM	10-100
SLAM	10-500
SAM	100-2000

	C-Scan		C-SAM	SLAM	SAM		
Frequency	1 MHz	10 MHz	30 MHz	100 MHz	200 MHz	500 MHz	1 GHz
Wavelength	1.5 mm			15 μ m			1.5 μ m
	<ul style="list-style-type: none"> -Medical ultrasound- -Conventional ultrasonic NDT- -Course grain metals: defect detection- -Cracks in plastic encapsulated IC devices- -Composite materials- -Cracks in ceramic IC packages- -Spot welds- -Heat sealing of food pouches- -Ceramic chip capacitors: delaminations and cracks- -Hermetic seal reliability- -Polymer-foil package lamination- -Integrated circuit die attach- -Thick film adhesion and porosity- -Laser spot welds- -Fine ceramics: defect detection- -Fine grain metals: defect detection- -Seam welds on tin cans- -Lead bonds on hybrid circuits- -Ceramic substrate porosity and cracks- -Cracks in silicon wafers- -Thin film adhesion- -Grain structure determination- -Fine line inspection on silicon- 						

Fig. 9 Comparison of acoustic microscopy applications with C-scan applications, based on transducer frequency and wavelength.

The most popular application of SLAM and C-SAM is the nondestructive evaluation of bonding, delamination, and cracks in materials. These instruments are often used for process and quality control, although a significant percentage of the devices are placed in analytical and failure analysis laboratories. The most popular application of SAM utilizes its very high magnification mode and is employed as a counterpart to conventional optical and electron microscopy, that is, to see fine detail at and near surfaces. The scanning acoustic microscope, like the other acoustic microscopy methods, produces image contrast, which is a function of the elastic properties of a material, where other nonacoustic techniques may not.

Composite Materials

Composite materials represent an exciting challenge for the materials scientist and for nondestructive testing. With the combination of materials having different properties and with manufactured anisotropy, acoustic microscopy can clearly define the relevant property distribution of materials at the microscopic level. The examples shown in this section are polymer materials reinforced with fibers. Metal-matrix composites and ceramic-matrix composites can be similarly studied.

In general, the combinations of materials having different mechanical properties result in interfaces that cause scattering of ultrasound and differential attenuation within the field-of-view. This can be important in determining the population density shifts of fibers within a sample.

SLAM Images. Acoustic microscopy can be used to differentiate fibers that are bonded well to the matrix from fibers that are separated from the matrix. Excessive stress, for example, would cause such a separation. As an example of this, Fig. 10 shows two nominally identical tensile-test bars made of carbon fiber reinforced plastic (CFRP). One of the bars has been stressed to a level that produced a 1.5% strain. The other sample has not been stressed. Figures 11(a) and 11(b) compare SLAM images of these samples at 100 MHz. The lighter image, Fig. 11(a), shows texturing that follows the fiber direction. Figure 11(b) shows the much darker, attenuating characteristics of the stressed sample. The excess attenuation is due to the separation of the fiber from the matrix.

Fig. 10 Photograph of two CFRP tensile-test bars--one unstressed and one stressed. The stressed bar was subjected to a force that yielded a 1.5% strain.

Fig. 11 100-MHz SLAM acoustic micrographs of the tensile bar samples shown in Fig. 10. (a) In the unstressed bar, the texture corresponds to fiber population shifts and small areas of disbond. (b) In the stressed bar that was pulled to a 1.5% strain level, there is no visible evidence of fracture. Field of view: both 3×2.25 mm. However, the increased acoustic attenuation (dark zones) present in (b) indicates stress damage to the

material.

Figure 11 in the article "Use of Color for NDE" in this Volume shows a 30-MHz transmission SLAM image of a Kevlar fiber-reinforced plastic that has been cut perpendicular to the fibers, thus producing extensive delamination (red) and cracks along the axis of the sample. Defects anywhere throughout the thickness will block the ultrasound transmission.

Figure 12 in this article shows a curved CFRP component. This sample is more difficult to image than the tensile-test bars because it has a complex shape; in addition, it has fibers oriented in a variety of different directions for directional strength.

Fig. 12 Complex-shaped CFRP component. The fibers are arranged to impart directional strength to certain critical areas of the sample.

In Fig. 13, a 30-MHz SLAM transmission image, a transition is seen between different fiber orientations in the sample; Fig. 14 in the article "Use of Color for NDE" in this Volume shows a large anomaly that is located in the middle of the curved portion. Scanning laser acoustic microscopy can be used to image complex-shape samples even though the curvature may cause some restriction of the field-of-view due to critical angle effects and lenslike action by the sample.

Fig. 13 30-MHz SLAM acoustic micrograph of the sample shown in Fig. 12. The left portion of the micrograph shows a more complex fiber network than the area on the right. A color image of the curved CFRP component is

shown in Fig. 14 in the article "Use of Color for NDE" in this Volume. Field of view: 14 × 10.5 mm

C-SAM Image. Figure 14 shows a 50-MHz reflection image in the C-SAM image of a CFRP tensile-test bar similar to that shown in Fig. 10. The acoustic lens is focused near the surface of the sample, and the electronic gate was set to receive a portion of the backscattered signal. Because the sample is constructed with fibers distributed throughout the volume, acoustic energy is scattered from all depths, and distinct, time-separated echoes were not generated. When the transducer was focused deep into the sample, there was less definition of the fibers in the acoustic image, similar to what is seen in the SLAM image.

Fig. 14 50-MHz C-SAM reflection mode micrograph of a CFRP test sample. The ultrasound was focused near the top surface of the sample. Field of view: 19 × 14 mm

Ceramic Materials

Ceramic materials are used in a variety of applications. Some are used in the electronics industry as substrates for delicate hybrid circuits. In structural applications, ceramics are used where high temperature and light weight are important. Silicon nitride, silicon carbide, and zirconia are receiving much attention for future engine applications. However, because of the inherent brittleness of ceramic materials, small defects are very critical to the structural integrity of the materials. The successful use of these materials necessitates careful nondestructive screening of the samples.

Aluminum Oxide. Figure 15 shows an optical picture of an aluminum oxide panel with laser-machined holes. This sample is an electronics-grade material that is 99.5% pure and has very low porosity. When the ceramic powder is first compressed in the green state, opportunities arise for segregated low-density areas to occur. After the sintering operation, these areas are usually found to be very porous. If one of these areas happens to coincide with the site of laser machining, the stresses that occur can cause the material to crack. Upon visual examination, it may be very difficult to detect fine cracks, even if they come to the surface. Dye penetrants can be used to increase the visual contrast. Unfortunately, in many applications, dyes are considered to be contaminants and therefore cannot be used for nondestructive testing. Because of the discontinuity in material property, a crack will reflect acoustic waves and produce high-contrast images.

Fig. 15 Aluminum oxide panel having laser-machined holes and slots with fine cracks around the perimeter and the circumference of the openings

Figure 16 shows a 100-MHz SLAM acoustic micrograph of a ceramic sample with a crack that can be seen as a dark line originating from one of the holes. Surrounding the area of the crack are several small, dark patches, which arise from localized increases in porosity. In the acoustic image, the pores may not be visible individually if they are smaller than the wavelength of sound. In this case, the pores are only a few microns in size, and the wavelength is about $25\text{ }\mu\text{m}$ (0.001 in.). The porous areas are detectable by virtue of excess ultrasound scattering, which causes the differential attenuation. Correlative analyses have shown that pores in the $1\text{ }\mu\text{m}$ (40 $\mu\text{in.}$) size range cause detectable attenuation increases (Fig. 16). However, the presence of a single $1\text{ }\mu\text{m}$ (40 $\mu\text{in.}$) pore would be difficult to detect unless the frequency of the ultrasound was increased to 1 GHz or more.

Fig. 16 100-MHz SLAM acoustic micrograph of an alumina panel section that contains a hole showing a crack with very high contrast. A digitally enhanced image of this alumina panel is also shown in Fig. 15 in the article "Use of Color for NDE" in this Volume. Field of view: $3 \times 2.25\text{ mm}$

It is significant to note that attenuation changes in ceramics correlate well with variations in strength (Ref 16). Fig. 15 in the article "Use of Color for NDE" in this Volume shows a digitally enhanced pseudocolor image of a ceramic sample that is useful for quantitative analysis of the gray scale and for identifying precisely the acoustic signal levels without relying on operator interpretation of the gray scale on the CRT screen.

Example 1: Use of C-SAM to Detect Internal Porosity Defects in an Alumina Ceramic Disk.

Acoustic microscopy is a powerful tool for nondestructively evaluating ceramic materials and displaying internal defects and density gradients such as porosity. An acoustic microscope scanning at 50 MHz with an f/1 lens on the transducer was used to evaluate a 6.4 mm (0.25 in.) thick aluminum oxide ceramic disk. No surface preparation of the sample was required prior to scanning.

The acoustic microscope, with a $25\text{ }\mu\text{m}$ (0.001 in.) acoustic resolution, scanned a $12.7 \times 12.7\text{ mm}$ ($0.50 \times 0.50\text{ in.}$) area of the ceramic disk. A pulse-echo technique (C-SAM) displayed internal reflections. The black areas (arrows, Fig. 17), which were detected as having the highest-amplitude reflection, indicate areas of porosity of the order of $10\text{ to }20\text{ }\mu\text{m}$ (400 to 800 $\mu\text{in.}$) in diameter.

Fig. 17 A portion of the 160 mm² (0.25 in.²) area of an alumina ceramic disk scanned by an acoustic microscope showing the presence of porosity in the disk (arrows). Courtesy of G.H. Thomas, Sandia National Laboratories

Example 2: Analysis of Alumina Ceramic Disks Supplied by a Variety of Manufacturers and Subjected to SLAM, C-SAM, and SAM Evaluation.

Disks of alumina were obtained from various manufacturers as part of a study on the effects of sintering temperature changes on mechanical strength and ultrasonic properties. The disks were approximately 25 mm (1 in.) diameter and 6 mm ($\frac{15}{64}$ in.) thick. Figure 18 shows a through-transmission 10-MHz SLAM image of an alumina disk. Higher SLAM frequencies could not be used, because of excessive attenuation. This is unusual for ceramic materials unless they are very porous or otherwise defective. Most of the area of this sample is nontransmissive (dark), which indicates a large internal defect. A subsequent cross section of this part, shown in Fig. 19, reveals a large crack that correlated to the indication in the SLAM image. The crack is not parallel to the surface; this was not known prior to cross sectioning.

Fig. 18 Low-frequency 10-MHz SLAM image of a 25 mm (1 in.) diam alumina test disk. The disk is very attenuating to ultrasound because of internal defects that cover about 75% of the area (dark zones). Field of view: 35 × 26 mm

Fig. 19 Cross sectioning of the alumina test disk shown in Fig. 18 reveals a large crack that correlates with the area of low acoustic transmission. This confirms the presence of an internal defect.

Figures 16(a) and 16(b) in the article "Use of Color for NDE" in this Volume are 15-MHz reflection C-SAM images of the same part focused to different depths. The radical changes in echo pattern at different depth locations in the disk result in widely different images. This is due to the nonparallel nature of the crack. In these figures, the darkest features correspond to the greatest echo amplitude. The C-mode scanning acoustic microscope clearly shows anomalies in this part, and by sequential scanning at a variety of depths, an overall diagnosis of the part can be assembled.

Figure 20 shows a SAM image produced at 180 MHz in which the lens was focused slightly below the surface ($20\text{ }\mu\text{m}$, or $800\text{ }\mu\text{in.}$, in water) to highlight subsurface information. The predominant features in Fig. 20 are surface scratches, which may also be associated with near-surface cracks. The grain structure and porosity of this sample are finer than can be visualized at 180 MHz.

Fig. 20 SAM image at 180 MHz of the sample shown in Fig. 18 and 19 revealing features of the ceramic at and near the surface. Color images of this disk are shown in Figures 16(a) and 16(b) in the article "Use of Color for NDE" in this Volume. Field of view: $1 \times 1\text{ mm}$

Another alumina sample produced under different conditions was found to be much more transparent acoustically. Figure 21 shows a 30-MHz SLAM image of a typical area of this disk. The higher frequencies are associated with higher magnifications and therefore smaller fields-of-view. The ceramic appears fairly homogeneous at this level of magnification. Figure 22, a 100-MHz SLAM image of the sample in Fig. 21, shows that some textural inhomogeneities are beginning to appear. The texture may be due to nonuniform segregation of porosity in the sample and throughout its thickness. Figure 23, a 50-MHz C-SAM image of the disk, shows large pores (white) about 1 mm (0.04 in.) below the surface. Figure 24 shows a 180-MHz SAM image made under conditions identical to Fig. 20. The fine texture at the surface of this sample is due to porosity. The differences between the two samples are clearly evident acoustically.

Fig. 21 SLAM images at 30 MHz of an alumina test disk similar in size to that shown in Fig. 18. This sample was quite transparent to the ultrasound, as evidenced by the bright, relatively uniform appearance of the acoustic image. Field of view: 14 × 10.5 mm

Fig. 22 SLAM 100-MHz transmission acoustic image of the sample shown in Fig. 21. At this higher frequency, textured variations in the sample are evident that may be due to micro (subresolution) porosity segregations, which cause differential absorption. Field of view: 3.5 × 2.6 mm

Fig. 23 C-SAM reflection mode image at 50 MHz made by setting the gate and focus to about 1 mm (0.04 in.) below the surface. The white circular spots correspond to individual pores located at this depth. Field of view: 30 × 30 mm

Fig. 24 SAM surface mode image at 180 MHz made under conditions identical to Fig. 20. In this image, the fine texture corresponds to porosity of the sample. Note the sharp contrast between the microstructure of this sample and that of Fig. 20. Field of view: 1×1 mm

Metals

In typical optical microscopy and metallography, it is necessary to polish and etch a sample to reveal the microstructural pattern. With SAM, this may not be necessary, as evidenced by the above. As one further illustration of SAM, Fig. 25 shows a 400-MHz image, focused $23 \mu\text{m}$ ($920 \mu\text{in.}$) below the surface, of a manganese-zinc ferrite material. The different phases of this important material can be visualized without the use of etchants. For certain metallic samples, that is, those with smooth, polished surfaces, SAM can be used for nondestructive testing as well as for metallographic analysis.

Fig. 25 SAM surface mode image at 400 MHz of a manganese-zinc ferrite sample that was polished metallurgically but not chemically etched. The elastic property differences between the various phases of this material are responsible for the contrast shown in this image. Courtesy of Honda Electronics Company, Ltd.

Figure 26 shows the metallographic structure of low-carbon steel; the specimen was polished but not etched. Although the images are similar to optical displays, the acoustic microscope is sensitive to acoustic properties and will generate images of surface and subsurface structure. The low-carbon steel was scanned at 1.3 GHz over an area measuring $100 \times 100 \mu\text{m}$ (0.004×0.004 in.). A high-resolution scanning acoustic microscope was used to generate this image from variations in the acoustic properties of the steel sample. Details of the grain structure, grain boundaries, and impurities in the specimen are visible in Fig. 26. The darker areas indicate contaminants trapped in the metal.

Fig. 26 SAM image at 1.3 GHz of a polished but unetched manganese-zinc low-carbon steel. Darker regions indicate the presence of typical contaminants trapped in the metal. Courtesy of G.H. Thomas, Sandia National Laboratories

Microelectronic Components

In the field of microelectronics, reliability is affected by tiny defects that may be harbored within a component or assembly but that are not detectable by electrical testing. The defects may grow with time or with thermal cycling, and when they reach a critical size, electrical performance may be affected; that is, a connection may break, or an electrical characteristic may change. Integrated circuits, ceramic capacitors, and thyristors that contain defects of this type will be examined in this section.

Integrated Circuits (ICs). A typical silicon IC chip (die) generates heat during its normal operation. The heat must be dissipated to stabilize the electrical behavior of the semiconductor. Therefore, the die is bonded onto a thermally conductive substrate, such as copper, aluminum oxide, or beryllium oxide. A high-reliability IC must also be hermetically sealed from ionic contamination and moisture in the atmosphere; therefore, a sealed ceramic or ceramic/metal package is used to house the die and to serve as an interconnection vehicle. Figure 27 shows a typical ceramic IC package containing a die bonded to a gold-plated surface. The die bond is also referred to as a die-attach.

Fig. 27 Typical ceramic-packaged IC showing the silicon die, which is bonded to the metallized surface

To complete the component, tiny interconnection wires are attached from the die to the corresponding metallization sites (bond pads) inside the ceramic package. A metal cover (lid) is then soldered to the top of the package. Apart from defects in the silicon chip itself, the life of the component depends on the quality of the die-attach, the integrity of the interconnection wire bonds, and the lid seal, all of which require good bonding.

Conventional Radiography Limitations. Because of its wide acceptance, conventional or x-ray radiography has usually been the first method of investigation for virtually all internal examinations (see the article "Radiographic Inspection" in this Volume). However, it has finally been realized that x-ray techniques indicate only the presence, absence, and density of materials through which the beam passes. On the positive side, if a poor bond is caused by the absence of a material, for example, solder, there will be less x-ray absorption and therefore a correct indication of a defect. However, if all the materials are present and in their proper proportions, there can be no differential x-ray absorption and no defect identification.

For example, suppose that the die is uniformly coated with solder but that there is no adhesion of the solder to the substrate due to contamination of the surface or improper metallurgy. Suppose also that the solder bonds well to the die and to the metallic layer but that for some reason the metallic layer becomes detached from the substrate. Both of these conditions are common problems that cannot be detected by x-ray but, because of the thin interface air gaps, cause complete reflection of ultrasound from, and no transmission of ultrasound across, the interface (Ref 17). The U.S. military standards for the inspection of circuits now include acoustic microscopy inspection (Ref 18).

Another common situation involves a die-attach material, such as epoxy, that is not very absorptive to x-rays, as is the typical lead tin solder alloy. If the die is bonded to a ceramic substrate that is also not very absorptive, low-energy x-rays can be used to detect voids (but not delaminations) in the die-attach material. However, if the die is attached to a metal substrate that absorbs x-rays, much higher energy is required for penetration. In this case, the die-attach material absorption becomes a negligible fraction of the total absorption signal, and neither disbonds nor voids can be detected.

Advantages of Acoustic Microscopy. The die-attach can be inspected by SLAM techniques in those cases in which ultrasound can be coupled to the top and bottom surfaces of the IC, that is, when there is no lid enclosing the package. When the lid is on, the air gap within the die cavity precludes the transmission of ultrasound, and a reflection method, such as C-SAM must be used. This is not true for plastic packages, for which SLAM and C-SAM can be used.

Figure 28 illustrates the SLAM inspection of an IC. Figure 29 shows a transmission SLAM image of a die-attach. The dark zones represent little or no ultrasound transmission. A white line generated by the SLAM image analysis system outlines the die region.

Fig. 28 Schematic illustrating use of the SLAM through transmission technique to evaluate the die-attach bond between the silicon die and the ceramic package

Fig. 29 30-MHz transmission SLAM image of a die-attach. The dark areas of the image correspond to little or no acoustic wave transmission due to the lack of bonding between the die and the ceramic. The white rectangle outlining the die is generated by an acoustic image analysis computer, which is used to determine the percent area of disbond. A 50-MHz reflection mode C-SAM color image of this integrated circuit is shown in Fig. 13 in the article "Use of Color for NDE" in this Volume. Field of view: 14 × 10.5 mm

Figure 30 shows the SLAM data after digital processing to highlight the areas of bond (white) and disbond (black). Because of its real-time imaging speed, the scanning laser acoustic microscope would be useful for quality control inspection of the die-attach before a ceramic IC is completely assembled.

Fig. 30 Computer-analyzed SLAM acoustic image of Fig. 29 in which the disbonds are clearly displayed as

black. A 50-MHz reflection mode C-SAM color image of this IC is shown in Fig. 13 in the article "Use of Color for NDE" in this Volume.

Figure 31 illustrates the inspection of an IC within a closed, hermetic package by means of C-SAM. In this case, the ultrasound accesses the die-attach interface through the ceramic substrate. Access through the lid is precluded by the air gap. Because of the differences in acoustic impedance, Z , between the ceramic and silicon materials, an echo will be returned from the die-attach interface in the case of a good bond or a bad bond, although the amplitudes of the echoes may be different. The acoustic impedances of a few typical materials are listed below:

Material	Acoustic impedance, 10^6 rayl
Air, vacuum	0
Water	1.5
Plastic	2.0-3.5
Glass	15
Aluminum	17
Silicon	20
Beryllia	32
Copper	42
Alumina	21-45
Tungsten	104

Fig. 31 Schematic illustrating use of the C-SAM reflection technique to evaluate the die-attach bond between the silicon die and the ceramic package of a ceramic dual-in-line package IC. With this technique, the ultrasound access to the bond layer is obtained by applying the pulse to the ceramic package, rather than through the lid, to avoid the air gap over the die.

More complete information on acoustic impedances can be found in Ref 19. If the amplitude of an echo relative to the amplitude of the incident acoustic pulse is denoted by R , then the value of R can be easily determined by the formula:

$$R = \frac{Z_2 - Z_1}{Z_2 + Z_1} \quad (\text{Eq 1})$$

where Z_1 is the acoustic impedance of the material through which the ultrasound is traveling before reaching the interface and Z_2 is the acoustic impedance of the material encountered on the other side of the interface. Using Eq 1 and considering the interface materials to be alumina ($Z_1 = 35$) and silicon ($Z_2 = 20$) a good bond will have an R value of 0.27. In the case of a complete disbands $Z_2 = 0$ (for air) and the R value is 1.0. In interpreting C-SAM images, because the ratio of signal levels between good and bad will be 3.7, care must be exercised to calibrate the system on a known sample.

Fig. 13 in the article "Use of Color for NDE" in this Volume shows a reflection mode C-SAM image produced at 50 MHz of the sample shown in Fig. 29. To assist the low-contrast differentiation of typical black-and-white gray-scale images, the C-SAM data have been digitally processed and presented as a pseudo-color-enhanced image in which red indicates disbond. The time gate was selected for the die-attach interface; therefore, unbonded regions of the die do not appear in the image, because from the ceramic side, the ultrasound cannot differentiate the air gap surrounding the die from the air gap under the disbonded areas of the die. In the case of unknown materials or in the case of not having an appropriate calibration sample, it may be more difficult to differentiate the bond versus the nobond condition because of nearly equal echo levels. Therefore, it is usually suggested to remove the lid from one sample of the lot and perform SLAM imaging. With SLAM, the amplitude of signal transmission across a two-material interface, T , is governed by:

$$T = 1 - R \quad (\text{Eq 2})$$

In the case of a good bond, $T = 0.73$, and in the case of a bad bond $T = 0$. The ratio of signal levels is limited only by the dynamic range of the instrument and can be typically 1000:1. To clarify this further, the ability of any electronic instrument to measure a zero signal level is determined by the signal-to-noise ratio of the instrument, which can typically exceed 60 dB.

Another important issue arises in ICs when the die is encapsulated in plastic molding compound instead of a ceramic package. In this case, both SLAM and C-SAM can be employed. When SLAM is employed, disbonds will appear nontransmitting and therefore dark (or whichever color is assigned). However, with C-SAM, more care must be taken in echo-level discrimination. The acoustic impedance of plastic is low ($Z = 3$) relative to ceramic; however, the echo magnitude from a plastic/air interface will still be 1.0. The echo from a plastic/silicon interface, however, will be 0.75, which is very close to 1.0, thus making the interpretation of echo level possibly difficult. Fortunately, however, the polarity of the echoes is different for air and silicon interfaces. In the case of $Z_2 > Z_1$ (plastic/silicon), the echo is positive and in the case of $Z_2 < Z_1$ (plastic/air), the echo is negative, according to Eq 2.

In the color-coded enhanced C-mode scanning acoustic microscope, the images can be displayed as echo-magnitude images or as echo-magnitude and polarity images (Ref 11). This is illustrated in Fig. 32 and in the article "Use of Color for NDE" (Fig. 12) in this Volume; both of these figures show a plastic-encapsulated IC that has disbonded areas between the plastic molding compound and the metal lead frame. As shown in Fig. 12 in the article "Use of Color for NDE," the color differentiation between positive echoes (blue) and negative echoes (disbond) (red) is essential for correctly diagnosing the integrity of this device. The echo signal levels from the plastic/lead frame interface are similar to the levels from the plastic/air gap interface; therefore, the good versus bad condition cannot be analyzed in the black-and-white presentation of Fig. 32. A through transmission SLAM image, such as that shown in Fig. 33, is clearer with regard to differentiating between bond (bright) and disbond (dark). A more thorough discussion of the acoustic microscopy analysis of plastic-encapsulated ICs can be found in Ref 20.

Fig. 32 C-SAM reflection mode image at 15 MHz of a plastic-encapsulated IC showing a suspicious area of the lead frame. In this image, the brightness of the image (towards white) represents the magnitude of the echoes from the interface. There is no regard for the polarity of the echoes. The color version of this image, shown in Fig. 12 in the article "Use of Color for NDE" in this Volume, is a dramatic improvement over the black-and-white image shown here and clearly differentiates the bonded regions from the unbonded regions of the lead frame.

Fig. 33 SLAM through transmission image produced at 10 MHz of sample shown in Fig. 32 of this article and Fig. 12 in the article "Use of Color for NDE" in this Volume. In this image, the disbonded zones are presented as dark. Careful analysis of Fig. 33 indicates that the disbonded areas in black-and-white are larger than those indicated in the color micrograph. This is explained by the fact that the scanning laser acoustic microscope shows the disbands on either side of the lead frame, that is, two interfaces, while the C-SAM image shows only one interface. When the IC was turned over and the opposite side of the lead frame examined, the SLAM and C-SAM information agreed. Field of view: 35 × 26 mm

At this point it should be mentioned that the interpretation of echoes is not always simple. Equations 1 and 2 are restricted to an interface of two thick materials. If there is a thin layer, echoes from the front and back surfaces of the thin layer will merge, and the resulting pulse shape will become distorted. More detailed analysis of the echo shape will be needed to determine the nature of the interface (Ref 21). Complete information on IC packaging is available in Ref 22.

Integrated Circuit Wire Bonding. Another problem with ICs is the connection of the tiny wires to the silicon chip. High-speed, densely spaced ICs may contain well over 300 leads. Traditional techniques of wire bonding use 0.018 mm (0.0007 in.) diam gold wires that are individually point-by-point stitch bonded from pads on the chip to pads on the package. Newer methods involve gang bonding, that is, the simultaneous bonding of a network frame of leads mechanically fixed in position by a polyimide film (tape). These are created by photo etching a pattern in a solid sheet of 0.025 mm (0.001 in.) thick copper that is bonded to the film. A sample produced by this method is shown in Fig. 34. This process, known as tape automated bonding (TAB), may soon become a widely used method for assembling ICs of all types.

Fig. 34 IC bonded to a frame of tiny leads that have been simultaneously bonded by a process known as tape automated bonding. This process is being used to perform interconnections on densely packed ICs having over 300 leads per chip.

In order for the process to become acceptable, however, the bond integrity of each lead must be ensured. With conventional stitch wire bonding, each wire can be stressed up to a few grams-force in a device called a nondestructive mode pull tester. Unfortunately, the high population density of TAB leads precludes pull testing, except in the case where the device is destroyed to measure the quality of the lead bonds. Acoustic microscopy, particularly SLAM, was determined to be a very reliable nondestructive test method (Ref 23, 24). The notion behind developing the test was that if the areas of bonding of the leads could be measured and if the areas of the bonds correlated with the mechanical strength of the bonds upon destruction, then the test method could be employed nondestructively on subsequent samples (Ref 25).

The good correlations described in Ref 23 and 24 are summarized and illustrated in the discussion that follows. Figures 35 and 36 show 200-MHz SLAM images of lead bonds on two IC chips. Some of the leads are bonded well, as indicated by the clear, bright areas, and other leads are obviously disbonded, completely or partially. Figure 37 shows a graph in which the area of bond, relative to a 100% maximum, is plotted for leads 1 through 68 around the perimeter of a chip. Pull strength relative to a maximum value of 100% is also given for each lead. The pull tests were performed to the point of failure of each lead, and the peak force was recorded. This acoustic microscopy procedure is under consideration as a standard test method for the military.

Fig. 35 SLAM acoustic image at 200 MHz of TAB-bonded leads on an IC. The bright areas at the tips of each lead indicate good-quality bonds. Field of view: 1.75×1.3 mm

Fig. 36 SLAM acoustic image at 200 MHz of TAB-bonded leads that are not of as uniform quality as those shown in Fig. 35. The poor bonds are mechanically weak and are more likely to suffer from long-term reliability problems. Field of view: 1.75×1.3 mm

Fig. 37 Plot of bond area percentage versus pin location to verify that SLAM bond strength analysis agrees with destructive pull tests. Graph shows the similarity between the relative strength of TAB-bonded leads, as determined by destructive pull tests, and the areas of bond, as determined by 200-MHz SLAM, on the same sample plotted as a function of location around the perimeter of an IC chip. The locations are denoted by pin numbers 1 through 68. Pressure readings for inner lead bonding are averages obtained for numerous samples that were tested.

Example 3: Use of SAM to Evaluate an IC on a Silicon Wafer.

Scanning acoustic microscopy offers a technique for generating high-resolution images of material structure and defects in ICs located on silicon crystal substrates. When the IC is scanned with a scanning acoustic microscope having a 2-GHz transducer, the image produced measures approximately $62 \times 62 \mu\text{m}$ ($0.0025 \times 0.0025 \text{ in.}$). This image displays the metallization on an IC. A high-resolution, pulse-echo scan shows 4 to 6 μm (160 to 240 $\mu\text{in.}$) wide aluminum lines deposited on a silicon substrate (Fig. 38). The small dark spots randomly scattered throughout the metallization are silicon nodules, which bubble up from the substrate, creating small defects in the conducting material. Depending on the focal depth, such structures as defects in the metallization, delaminations or disbonds between conductors, metal line thickness, and buried *p*-type material can be measured or imaged. The shaded fingers midway on the right side in Fig. 38 indicate doped material below the surface. No preparation of the sample prior to testing was necessary.

Fig. 38 Pulse-echo SAM micrograph of 4 to 6 μm (160 to 240 $\mu\text{in.}$) wide aluminum lines on the silicon substrate of an IC. Dark spots are silicon nodule defects, the source of which is silicon bubbling up from the substrate of the wafer. Courtesy of G.H. Thomas, Sandia National Laboratories, Livermore, CA

Ceramic capacitors are passive electronic components used in virtually every electronic circuit to store electrical charge. They are manufactured to be physically small, yet they must have very high capacitance values, which can be obtained with specially formulated, high dielectric constant materials. Figure 39 shows various miniature multilayer capacitors. The basic construction of a capacitor involves two parallel plate electrodes separated by a small distance that is occupied by the dielectric. Capacitance values are inversely proportional to the dielectric thickness and are proportional to the total area of the electrodes.

Fig. 39 Miniature ceramic capacitors constructed of multiple layers of high dielectric constant ceramic alternated with layers of conductive metallization. Relative size of single capacitor is evident when compared to the head of a match.

To increase the area in a small space, multiple layers are used and are electrically connected together in parallel. The problems associated with capacitors that cannot be detected electrically are internal cracks in the ceramic, large voids in the dielectric layers, delaminations between the layers, and high porosity of the dielectric ceramic material. This is illustrated in Fig. 40. Most ceramic capacitors have barium titanate in the dielectric formulation and are therefore x-ray opaque.

Fig. 40 Diagram illustrating the layered construction used in multilayer ceramic capacitors and the locations of potential defects in these electronic components

Ultrasound C-scan was suggested as a method for detecting flaws in ceramic capacitors (Ref 26). However, it was later found to be useful only for the large components because of edge effects that are characteristic of all C-scan and C-SAM images. Scanning laser acoustic microscope techniques are not necessarily limited by the edge effects, as illustrated in Fig. 41.

Fig. 41 Edge effect in (a) C-SAM and (b) SLAM. In the case of C-SAM, when the transducer is too close to the left edge of a sample having thickness t , the acoustic beam becomes cut off, and the echo signal does not return from the bottom surface (side view, upper figure). Assuming a ray angle of 45° , the edge of the sample cannot be inspected to within a distance t , thus limiting the area of scan of a sample (top view, lower figure). If the sample has a lateral dimension $D \leq 2t$, the focused reflection mode cannot be employed in a valid manner. By way of comparison, in the case of SLAM, because collimated energy is used, the edge effect is minor and limited only by diffraction of the illumination wave at the edges (also shown in side view, upper figure, and top view, lower figure).

Figure 42 shows a 30-MHz SLAM image of a ceramic capacitor that has a relatively uniform appearance in transmission. The dark circular spot is a delamination that was confirmed by destructive cross sectioning of the component, as shown in Fig. 43.

Fig. 42 SLAM image at 30 MHz of a plastic-encapsulated ceramic capacitor having a significant defect that can cause long-term reliability problems. This defect is not evident by electrical testing. Field of view: 14 × 10.5 mm

Fig. 43 Cross-sectional analysis of the capacitor shown in Fig. 42 revealing a delamination in the location indicated by SLAM. The cut edge of the capacitor was polished and placed under a conventional microscope.

The analysis of ceramic capacitors by SLAM has become a standard method for the nondestructive evaluation and screening of ceramic capacitors for internal defects (Ref 27). Investigations have been performed to correlate the information obtained nondestructively with that obtained by conventional destructive physical analysis. Quantitative data have been acquired and associated with the physical properties of the materials. Users of the technique have reported significant improvements in reliability as a result of the SLAM screening of parts.

Silicon Thyristors. The silicon thyristor, which is basically three close coupled *p-n* junctions in the form of a *p-n-p-n* structure, is an important switching device. The thyristor has two stable states: the on state with high current and low voltage and the off state with low current and high voltage. Because of its two stable states and the low power dissipation in these two states, the thyristor has unique applications ranging from speed control in home appliances to switching and power inversion in high-voltage transmission lines. The following example illustrates the use of acoustic microscopy to evaluate whether or not a thyristor has been correctly assembled and will operate according to design specifications.

Example 4: Use of Acoustic Microscopy to Evaluate Gate-Turnoff Silicon-Controlled Thyristor Integrity.

The performance of 77 mm (3.0 in.) diam, 5-kV, 2-kA silicon power thyristors is dependent on good electrical attachment between the gate array and the underlying silicon device. Gate-turnoff (GTO) thyristors are fabricated by the solid-state attachment of a conducting pattern between one large [100] cut silicon wafer and two smaller concentric annular wafer segments also having [100] cut orientations. Both the underlying wafer and the annular segments are 0.51 mm (0.020 in.) thick. The large underlying wafer is 77 mm (3.0 in.) in diameter, and the larger-diameter annulus is approximately 51 mm (2.0 in.) in diameter. The successful fabrication of this silicon-controlled power device requires that the conducting patterns be of good quality, that the wafers be intact (no cracks), and that the bonds be well attached.

Acoustic microscopy was chosen to inspect the conducting patterns at the interface between the overlying annuli and the underlying silicon wafer. The surfaces presented to the interrogating ultrasonic beam were lapped and coated with approximately 1.0 μm (40 $\mu\text{in.}$) of gold for good electrical contact.

The images shown in Fig. 44 were made by focusing a 50-MHz beam on the interface between the annuli and the underlying wafer. This produced a resolution spot size of approximately 100 μm (0.004 in.). The beam was then scanned, and a 1024 × 1024 pixel image was acquired by recording and displaying the echo from the described interface.

Fig. 44 Thyristor gate arrays imaged through 0.51 mm (0.020 in.) of overlying [100] cut silicon. The annular rings combined with the underlying silicon wafer make up a 5-kV, 2-kA gate-turnoff power device. (a) This device shows well-attached and well-formed finger arrays. (b) This device shows poorly formed and poorly attached arrays. The cracked spacer ring is not critical to the operation of (a) but was included to display cracks as they would appear if the array annuli had cracked. Courtesy of R.S. Gilmore, General Electric Research and Development Center

Figure 44 shows two silicon-controlled GTO thyristors that contain most of the desirable and undesirable features that can be produced in the fabrication of a silicon power device. The device in Fig. 44(a) shows well-developed finger arrays except for the two outer fingers at the approximate three o'clock position in the inner ring. A silicon spacer ring used to keep the two annuli centered was badly cracked, but this ring will be removed in a subsequent fabrication operation. The spacer ring is included in this image to show how cracks would appear in the silicon. The device in Fig. 44(b) shows very poorly formed finger arrays, and the resulting device would probably be inoperable if it were assembled and tested. This nondestructive evaluation of GTO thyristors demonstrated that acoustic microscopy is a valuable tool for the process and quality control of silicon power devices.

Use of Color for NDE

Introduction

MAJOR DEVELOPMENTS in digital electronics have led to the commercial availability of a wide range of specialized devices for image processing and enhancement. With digital image enhancement systems, data interpretation becomes easier, difficult-to-detect features are more readily discernible, and quantitative analysis is possible. Among the numerous image-processing operations available (see the article "Digital Image Enhancement" in this Volume), color-enhanced images produce some of the more valuable, if not spectacular, results.

Use of Color for NDE

Color Images

This collection of color images is intended to assist the reader in recognizing the advantages and/or limitations of pseudocolor in NDE. This collection both complements and supplements articles in this Handbook that describe in detail the principles and applications of methods that utilize color for discontinuity characterization. Numerous comparisons are made between figures appearing in color in this section and their black-and-white counterparts found elsewhere in this Volume. The types of color images appearing in this article include:

Inspection method	Fig. No.
Ultrasonic inspection	2, 3, 6(c), 6(d), 10, 21, 23
Acoustic microscopy	5, 11, 12, 13, 14, 15, 16
Thermal analysis	17, 18, 19, 20, 22
Computed tomography	1, 7, 8, 9
Digital radiography	6(a), 6(b)
Stress analysis^(a)	24

- (a) The photoelastic fringe patterns shown in Fig. 24 are the result of stress/strain analysis. See the article "Strain Measurement for Stress Analysis" for details.

Fig. 1 Computed tomographic reconstruction of a 9-V battery. (a) Image reconstructed from 500 views showing evidence of undersampling. (b) Image reconstructed from 1000 views, the data filtered with a Wiener filter before backprojection to correct for the point spread of the beam. (T.N. Claytor, Los Alamos National Laboratory)

Fig. 2 Linear histogram equalization (image enhancement technique) of a low-contrast ultrasonic image of a bond line in an explosively bonded steel-to-aluminum plate. The detonation wave travels from top to bottom, with higher values of intensity indicating better bonding. (a) and (b) Digitized image with 64 levels and corresponding histogram. (c) and (d) After the histogram equalization process, the colors are more widely separated so that the subtler features of the bonding can be seen. (T.N. Claytor, Los Alamos National Laboratory)

Fig. 3 Effects of a low-pass filter and a median filter on a slightly noisy ultrasonic image of a cross-rolled tungsten plate with internal rolling tears. (a) The original image has point noise and horizontal streaks. (b) After low-pass filtering, the point noise has been eliminated, but the streaks are still visible. (c) After median filtering, the point noise is eliminated, the streaks are less prominent, and the sharpness of the original image is preserved. (T.N. Claytor, Los Alamos National Laboratory)

Fig. 4 Palettes useful for black-and-white and color presentation of data. (a) Standard linear gray scale. (b) Gray scale with a red threshold for identifying out-of-bound conditions. (c) The most colorful palette spectrum. (d) and (e) Complementary palettes. (T.N. Claytor, Los Alamos National Laboratory)

Fig. 5 50-MHz acoustic microscope image of a stainless steel-to-stainless steel diffusion bond with a silver interlayer. The blue, white, and black areas indicate poorer bonding. The pattern displayed in this image matched the ductile/brittle pattern on the fracture surface. (G.H. Thomas, Sandia National Laboratories)

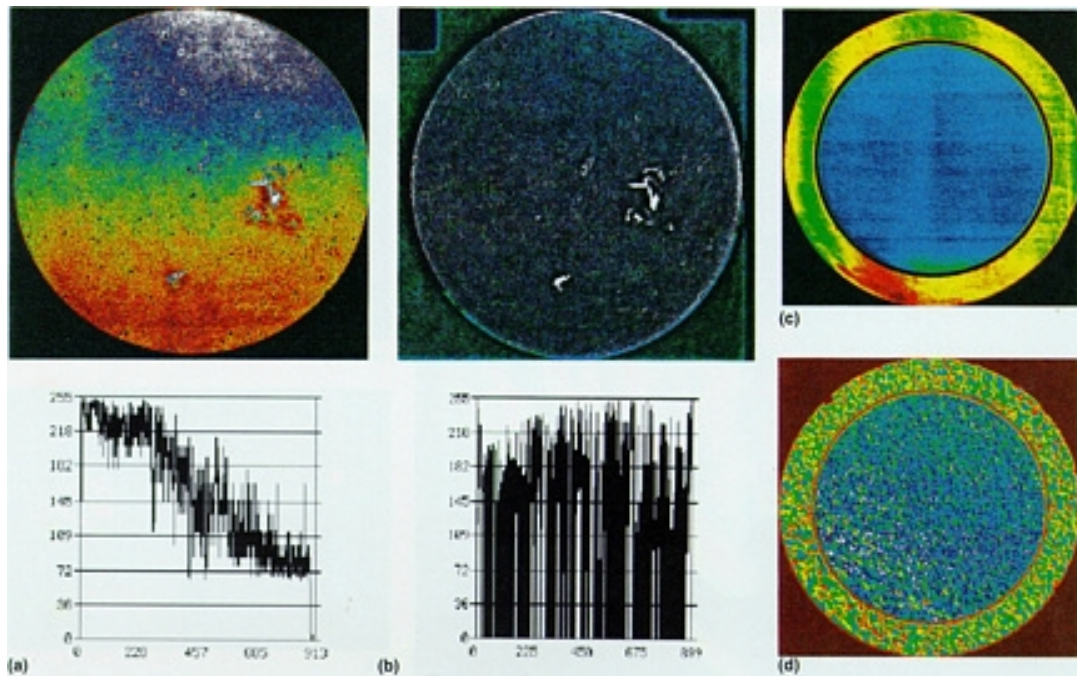

Fig. 6 Examples of contrast enhancement techniques. (a) Radiograph and corresponding line density chart of a ceramic disk containing inclusions (white) and voids (dark areas). (b) After a field-flattening contrast enhancement procedure, the large voids and inclusions are more easily detected at the expense of smaller voids. (c) Ultrasonic image of a HIPed tungsten plate showing density variations enhanced by the use of color. (d) Ultrasonic image of a hot-rolled tungsten plate showing texture variations. Compare Fig. 6(c) and 6(d) with Fig. 6 and 7 in the article "Digital Image Enhancement." (T.N. Claytor, Los Alamos National Laboratory)

Fig. 10 Representations of two-dimensional data in a three-dimensional format. (a) Ultrasonic image of defects in circuit board pads. (b) C-scan of a filament-wound vessel with defects. (T.N. Claytor, Los Alamos National Laboratory)

Fig. 11 30-MHz SLAM acoustic image of a Kevlar-reinforced composite test coupon with delamination and cracks. The damage was induced by cutting the bar perpendicular to fibers. The extent of the damage is shown by the ingress of color, with red/green indicating the most extensive damage. The colors are associated with levels of acoustic transmission. A high level (white) indicates a homogeneous material, while a lower level (red/green) indicates discontinuities. (L.W. Kessler, Sonoscan, Inc.)

Fig. 12 15-MHz C-SAM reflection mode image of a plastic-encapsulated integrated circuit showing defects in the lead frame. In this image, the echo polarity information is presented by color scale changes in which disbonds are red (negative polarity) and good bonds (positive echoes) are blue. Without this polarity information, it is difficult to make a correct interpretation of the bonding condition in this sample (see Fig. 32 in the article "Acoustic Microscopy"). (L.W. Kessler, Sonoscan, Inc.)

Fig. 13 50-MHz C-SAM reflection mode image of the same die-attach sample shown in Fig. 29 and 30 in the article "Acoustic Microscopy." In this image, areas of disbond are indicated by the color red. (L.W. Kessler, Sonoscan, Inc.)

Fig. 14 30-MHz SLAM acoustic micrograph of the carbon fiber reinforced polymer component shown in Fig. 13 of "Acoustic Microscopy." Long, irregular defect (arrow) corresponds to blistering of one of the laminates. (L.W. Kessler, Sonoscan, Inc.)

Fig. 15 100-MHz SLAM micrograph of the alumina panel shown in Fig. 16 in the article "Acoustic Microscopy." Color is used to delineate a crack with a specific acoustic brightness level. (L.W. Kessler, Sonoscan, Inc.)

Fig. 16 15-MHz reflection mode C-SAM images of internal defects in the alumina test disk shown in Fig. 18 in the article "Acoustic Microscopy." In (a), the darker features correspond to higher-magnitude echo levels than the yellow. In (b), the focus and gate levels were changed slightly. Because the defects are not parallel to the surface of the part, echoes will not return at different times; therefore, a fixed-gate position will show echoes only at the depth selected. (L.W. Kessler, Sonoscan, Inc.)

Introduction

IN FORGINGS of both ferrous and nonferrous metals, the flaws that occur most often are caused by conditions that exist in the ingot, by subsequent hot working of the ingot or the billet, and by hot or cold working during forging. The nondestructive inspection (NDI) methods most commonly used to detect these flaws include visual, magnetic particle, liquid penetrant, ultrasonic, eddy current, and radiographic inspection. This article discusses the applications of these methods to forgings. Information on the equipment and techniques used in these inspection methods is available in the articles so titled in this Volume.

Nondestructive Inspection of Forgings

Flaws Originating in the Ingot

Many large open-die forgings are forged directly from ingots. Most closed-die forgings and upset forgings are produced from billets, rolled bar stock, or preforms. Many, though by no means all, of the imperfections found in forgings can be attributed to conditions that existed in the ingot, sometimes even when the ingot has undergone primary reduction prior to the forging operation. Some, but again by no means all, of the service problems that occur with forgings can be traced to imperfections originating in the ingot.

Chemical Segregation. The elements in a cast alloy are seldom distributed uniformly. Even unalloyed metals contain random amounts of various types of impurities in the form of tramp elements or dissolved gases; these impurities are also seldom distributed uniformly. Therefore, the composition of the metal or alloy will vary from location to location. Deviation from the mean composition at a particular location in a forging is termed segregation. In general, segregation is the result of solute rejection at the solidification interface during casting. For example, the gradation of composition with respect to the individual alloying elements exists from cores of dendrites to interdendritic regions. Segregation therefore produces a material having a range of compositions that do not have identical properties.

Forging can partially correct the results of segregation by recrystallizing or breaking up the grain structure to promote a more homogeneous substructure. However, the effects of a badly segregated ingot cannot be totally eliminated by forging; rather, the segregated regions tend to be altered by the working operation, as shown in Fig. 1.

Fig. 1 Microstructural bonding due to chemical segregation and mechanical working

In metals, the presence of localized regions that deviate from the nominal composition can affect corrosion resistance, forging and joining (welding) characteristics, mechanical properties, fracture toughness, and fatigue resistance. In heat-treatable alloys, variations in composition can produce unexpected responses to heat treatments, which result in hard or soft spots, quench cracks, or other flaws. The degree of degradation depends on the alloy and on process variables. Most metallurgical processes are based on an assumption that the metal being processed is of a nominal and reasonably uniform composition.

Ingot Pipe and Centerline Shrinkage. A common imperfection in ingots is the shrinkage cavity, commonly known as pipe, often found in the upper portion of the ingot. Shrinkage occurs during freezing of the metal, and eventually there is insufficient liquid metal near the top end to feed the ingot. As a result, a cavity forms, usually approximating the shape of a cylinder or cone--hence the term pipe. Piping is illustrated in Fig.

2. In addition to the primary pipe near the top of the ingot, secondary regions of piping and centerline shrinkage may extend deeper into an ingot (Fig. 3).

Fig. 2 Schematic showing piping in top-poured ingots

Fig. 3 Longitudinal section through an ingot showing extensive centerline shrinkage

Primary piping is generally an economic concern, but if it extends sufficiently deep into the ingot body and goes undetected, it can eventually result in a defective forging. Detection of the pipe can be obscured in some cases if bridging has occurred.

Piping can be minimized by pouring ingots with the big end up, by providing risers in the ingot top, and by applying sufficient hot-top material (insulating refractories or exothermic materials) immediately after pouring. These techniques extend the time that the metal in the top regions of the ingot remains liquid, thus minimizing the shrinkage cavity produced in this portion of the ingot.

On the other hand, secondary piping and centerline shrinkage can be very detrimental because they are harder to detect in the mill and may subsequently produce centerline defects in bar and wrought products. Such a material condition may indeed provide the flaw or stress concentrator for a forging burst in some later processing operation or for a future product failure.

High Hydrogen Content. A major source of hydrogen in certain metals and alloys is the reaction of water vapor with the liquid metal at high temperatures. The water vapor may originate from the charge materials, slag ingredients and alloy additions, refractory linings, ingot molds, or even the atmosphere itself if steps are not taken to prevent such contamination. The resulting hydrogen goes into solution at elevated temperatures; but as the metal solidifies after pouring, the solubility of hydrogen decreases, and it becomes entrapped in the metal lattice.

Hydrogen concentration in excess of about 5 ppm has been associated with flaking, especially in heavy sections and high-carbon steels. Hydrogen flakes (Fig. 4) are small cracks produced by hydrogen that has diffused to grain boundaries and other preferred sites, for example, inclusion/matrix interfaces. However, hydrogen concentrations in excess of only 1 ppm have been related to the degradation of mechanical properties in high-strength steels, especially ductility, impact behavior, and fracture toughness.

Fig. 4 Hydrogen flaking in an alloy steel bar. (a) Polished cross section showing cracks due to flaking. (b) Fracture surface containing hydrogen flakes. Note the reflective, faceted nature of the fracture. (c) SEM micrograph showing the intergranular appearance of the flakes in this material

Metals can also possess a high hydrogen content without the presence of flakes or voids. In this case, the hydrogen may cause embrittlement of the material along selective paths, which can drastically reduce the resistance of a forged part to crack propagation resulting from impact loading, fatigue, or stress corrosion.

In cases where hydrogen-related defects can serve as the initiation site for cracking and thus increase the likelihood of future failures, it is advisable to use a thermal treatment that can alleviate this condition. For example, slow cooling immediately following a hot-working operation or a separate annealing cycle will relieve residual stresses in addition to allowing hydrogen to diffuse to a more uniform distribution throughout the lattice and, more important, to diffuse out of the material.

Nonmetallic inclusions, which originate in the ingot, are likely to be carried over to the forgings, even though several intermediate hot-working operations may be involved. Also, additional inclusions may develop in the billet or in subsequent forging stages.

Most nonmetallic inclusions originate during solidification from the initial melting operation. If no further consumable-remelting cycles follow, as in air-melted or vacuum-induction products (with no remelting cycle to follow), the size, frequency, and distribution of the nonmetallic inclusions will not be altered or reduced in size or frequency during further processing. If a subsequent vacuum-remelting operation is used, the inclusions will be lessened in size and frequency and will become more random in nature. If an electroslag-remelting cycle is used, a more random distribution of inclusions will result.

Two kinds of nonmetallic inclusions are generally distinguished in metals:

- Those that are entrapped in the metal inadvertently and originate almost exclusively from particles of matter that are occluded in the metal while it is molten or being cast
- Those that separate from the metal because of a change in temperature or composition

Inclusions of the latter type are produced by separation from the metal when it is in either the liquid or the solid state. Oxides, sulfides, nitrides, or other nonmetallic compounds form droplets or particles when these compounds are produced in such amounts that their solubility in the matrix is exceeded.

Air-melted alloys commonly contain inclusions mainly of these chemical characteristics. Vacuum- or electroslag-remelted alloys more commonly contain conglomerates of any of these types, frequently combined with carbon or the hardening element or elements that precipitate during stabilization and aging cycles to form inclusions such as titanium carbonitrides or carbides. Homogenizing cycles are normally used for the ingot prior to conversion or at an early stage of conversion.

Because these compounds are products of reactions within the metal, they are normal constituents of the metal, and conventional melting practices cannot completely eliminate such inclusions. However, it is desirable to keep the type and amount of inclusions to a minimum so that the metal is relatively free from those inclusions that cause the most problems.

Of the numerous types of flaws found in forgings, nonmetallic inclusions appear to contribute significantly to service failures, particularly in high-integrity forgings such as those used in aerospace applications. In many applications, the presence of these inclusions decreases the ability of a metal to withstand high static loads, impact forces, cyclical or fatigue loading, and sometimes corrosion and stress corrosion. Nonmetallic inclusions can easily become stress concentrators because of their discontinuous nature and incompatibility with the surrounding composition. This combination may very well yield flaws of critical size that, under appropriate loading conditions, result in complete fracture of the forged part.

Unmelted electrodes and shelf are two other types of ingot flaws that can impair forgeability. Unmelted electrodes (Fig. 5a) are caused by chunks of electrodes being eroded away during consumable melting and dropping down into the molten material as a solid. Shelf (Fig. 5b) is a condition resulting from uneven solidification or cooling rates at the ingot surfaces.

Fig. 5 Sections through two heat-resistant alloy ingots showing flaws that can impair forgeability. (a) Piece of unmelted consumable electrode (white spot near center). (b) Shelf (black line along edge) resulting from uneven solidification of the ingot

The consumable-melting operation has occasionally been continued to a point where a portion of the stinger rod is melted into the ingot, which may be undesirable because the composition of the stinger rod may differ from that of the alloy being melted. To prevent this occurrence, one practice is to weld a wire to the stinger rod, bend the wire down in tension, and weld the other end of the wire to the surface of the electrode a few inches below the junction of the stinger rod and the electrode. When the electrode has been consumed to where the wire is attached to it, the wire is released and springs out against the side of the crucible, thus serving as an alarm to stop the melting. A disadvantage of this practice is that the wire may become detached and contaminate the melt.

Nondestructive Inspection of Forgings

Flaws Caused by the Forging Operation

Flaws produced during the forging operation (assuming a flaw-free billet or bar) are the result of improper setup or control. Proper control of heating for forging is necessary to prevent excessive scale, decarburization, overheating, or burning. Excessive scale, in addition to causing excessive metal loss, can result in forgings with pitted surfaces. The pitted surfaces are caused by the scale being hammered into the surface and may result in unacceptable forgings.

Severe overheating causes burning, which is the melting of the lower melting point constituents. This melting action severely reduces the mechanical properties of the metal, and the damage is irreparable. Detection and sorting of forgings that have been burned during heating can be extremely difficult.

In many cases, the flaws that occur during forging are the same as, or at least similar to, those that may occur during hot working of the ingots or billets; these are described in the previous section.

Internal flaws in forgings often appear as cracks or tears, and they may result either from forging with too light a hammer or from continuing forging after the metal has cooled down below a safe forging temperature. Bursts, as described above, may also occur during the forging operation.

A number of surface flaws can be produced by the forging operation. These flaws are often caused by the movement of metal over or upon another surface without actual welding or fusing of the surfaces; such flaws may be laps or folds (described previously).

Cold shuts often occur in closed-die forgings. They are junctures of two adjoining surfaces caused by incomplete metal fill and incomplete fusion of the surfaces.

Surface flaws weaken forgings and can usually be eliminated by correct die design, proper heating, and correct sequencing and positioning of the workpieces in the dies.

Shear cracks often occur in steel forgings; they are diagonal cracks occurring on the trimmed edges and are caused by shear stresses. Proper design and condition of trimming dies to remove forging flash are required for the prevention of shear cracks.

Other flaws in steel forgings that can be produced by improper die design or maintenance are internal cracks and splits. If the material is moved abnormally during forging, these flaws may be formed without any evidence on the surface of the forging.

Nondestructive Inspection of Forgings

Selection of Inspection Method

The principal factors that influence the selection of an NDI method for forgings include degree of required integrity of the forging, metal composition, size and shape of the forging, and cost. There are sometimes other influential factors, such as the type of forging method used.

For high-integrity forgings, it is often required that more than one inspection method be employed because some inspection methods are capable of locating only surface flaws; therefore, one or more additional methods are required for locating internal flaws. For example, many forgings for aerospace applications are inspected with liquid penetrants (or with magnetic particles, depending on the metal composition) for locating surface flaws, then by ultrasonics for detecting internal flaws.

Certain characteristics or conditions unique to forgings can create service problems, yet these conditions are not easily detected by nondestructive inspection. Exposed end grain, which can lead to poor corrosion resistance or to susceptibility to stress-corrosion cracking, is the most prevalent of the undesirable conditions. The strength of the forging can be adversely affected if the grains flow in an undesirable direction (as in grain reversal) or if grain flow is confined to only a portion of the section being forged rather than being well distributed. Both exposed end grain and poor grain flow can be most effectively corrected by redesigning the forging or forging blank, particularly with regard to flash. It is virtually impossible to detect exposed end grain nondestructively; only rarely can poor grain flow be detected nondestructively.

Both conditions are much more readily analyzed by sectioning and macroetching sample forgings in preproduction stages of product development.

When certain steels or nonferrous alloys are forged at too high a temperature or sometimes when a part cools too slowly after forging, there is a potential for grain size in the finished forging to be excessively large. Such a condition is difficult to detect nondestructively, except with ultrasonics, and then only when the grains are very large. Even with very large grains, ultrasonic inspection cannot determine grain size quantitatively, nor can it detect large grains reliably. Only the possibility that large grains are present can be inferred from excessive attenuation of the ultrasonic beam.

Effect of Type of Forging

Many of the types of flaws that can occur in forgings do so without particular regard to the type of forging; that is, open-die, closed-die, upset, or rolled. However, there are many cases in which a specific type of flaw is more likely to occur in one type of forging than in another. Additional information on the types of forging processes discussed below is available in *Forming and Forging*, Volume 14 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*.

Open-Die Forgings. Most forgings produced in open dies are relatively large; therefore, their size is likely to impose some restrictions not only on the inspection method used but also on the system within a given inspection method. For large open-die forgings, NDI methods (other than visual) are generally limited to magnetic particle or liquid penetrant inspection (for surface discontinuities) or to ultrasonic inspection (for internal flaws). In general, the flaws likely to be found in open-die forgings are similar to those that may occur in other hot-worked shapes--with the exception of forging laps and cold shuts, which usually occur only in closed-die forgings.

Closed-Die and Upset Forgings. The discontinuities in closed-die forgings that can be detected by liquid penetrant inspection or magnetic particle inspection (if the forging is ferromagnetic) are the following:

- Forging laps, which can be caused by incorrect die design, use of incorrect size of forging stock, excessive local conditioning of forging stock for removal of surface flaws, and excessively sharp corners in the forging stock
- Seams, due to incomplete removal of seams from the forging stock
- Surface cracks, caused by incorrect forging temperature, nonductile metallic or nonmetallic segregates in the forging stock, or surface contamination from the furnace atmosphere or other contaminants in the furnace or on the forging (such as high-sulfur fuels for heating nickel alloys or leaded crayons used for marking parts before heating)
- Quench cracks
- Cold-straightening cracks

The likelihood that any of the above discontinuities will appear in a closed-die forging produced in a press or by upsetting is more prevalent than for hammer forgings, because press and upset forgings permit no opportunity to monitor the workpiece being forged during the forging operation. During hammer forging, the top surface of the forging is visible between hammer blows. The bottom surface may also be visible at times--particularly for large forgings that are raised intermittently during forging for descaling and lubricating the bottom surface or for forgings of temperature-sensitive alloys that are raised off the bottom die to permit heat recovery to the bottom surface.

Any seam in the forging stock or incipient laps or cracks will probably develop into significant forging laps or cracks if not detected during formation. Consequently, in hammer forging, a large percentage of such potentially scrap forgings can be removed from the production run and can either be salvaged by removing the discontinuity prior to finishing or scrapped at that point to avoid wasted forging time. Also, multiple-cavity hammer forgings permit inspection of the parts and blending out of minor laps or superficial cracks before finish forging.

Discontinuities that are not detectable by either magnetic particle or liquid penetrant inspection are noted in the following list. Most of these can be detected by ultrasonic inspection:

- Flakes, due to the absorption of hydrogen
- Pipe, due to center shrinkage in the ingot and subsequent insufficient reduction of forging stock

- Subsurface nonmetallic segregation
- Subsurface cracking, which may occur in certain alloys, particularly during the forging of irregular sections
- Weak centers in forging stock, caused by insufficient reduction from the ingot
- Subsurface cracks caused by forging material having comparatively cold centers, and generally occurring in large forging billets heated for insufficient time
- Rewelded forging laps, formed and rewelded during forging. With subsequent hammer blows, the lap forms, the scale is knocked or blown off, and the lapped metal rewelds, forming a healed lap with transverse grain flow and, possibly, entrapped scale

The presence of a rewelded forging lap in a suspected area can be checked by removing the surface metal below the decarburized layer and polishing this surface and swabbing with cold ammonium persulfate, thus revealing the decarburization at both sides of the lap (if present). The condition can be eliminated with corrections in blocker-die design.

Ring-Rolled Forgings. Discontinuities in forgings produced by ring rolling may be either inherited from the ingot or mechanically induced in forging operations, much the same as for forgings produced completely in hammers or presses. Inherited discontinuities are common to all products produced from bar or billet and can usually be traced back to the composition, cleanliness, or condition of the ingot. Although these discontinuities are not found only in ring-rolled forgings, they probably account for the vast majority of known discontinuities in ring-rolled forgings. Typical discontinuities are inclusions, porosity, hot-top remnants, and segregation.

Ultrasonic inspection is a reliable method of detecting the presence of inherited discontinuities. It is always advisable to inspect the material before it is ring rolled. Extremely large billets (1200 mm, or 48 in., in diameter and larger) may have surface conditions that cause problems relative to sound entry. Large billets may exhibit structural conditions, depending on the amount of reduction from the ingot, that are too large for a complete ultrasonic inspection. Smaller, well-worked billets can be examined at 2.25 MHz. The larger billets require the use of 1.0-MHz crystals, and even then ultrasonic penetration is not always possible.

Final proof that the forging is free of inherited discontinuities is accomplished through ultrasonic inspection of the completed forging. Depending on the final machined shape, certain ring-rolled forgings may require a preliminary ultrasonic inspection before final machining. When an extreme change in contour prevents a complete ultrasonic inspection of the final shape, inspection can be performed on portions of the forged ring.

Externally induced mechanical discontinuities that have been found in ring-rolled forgings include surface-related laps, cracks, and exfoliations. Normally, these discontinuities can be detected visually either during the manufacturing process or in the machined condition after rolling. However, ultrasonic inspection can be valuable for determining the depth of surface-related discontinuities and for detecting them even when they have been obscured by subsequent working or metal movement. Magnetic particle inspection is also used to detect surface-related, externally induced mechanical discontinuities in ferromagnetic ring-rolled forgings. Liquid penetrant inspection has often been successfully used to detect surface flaws in nonferromagnetic rings.

Mechanically induced internal discontinuities (known as strain-induced porosity) can occur in certain materials. Some nickel or titanium alloys have an inherent susceptibility to these types of discontinuities in portions of the ring stretched at critical temperatures. This may result from improper stock distribution, improper rolling techniques, or improper tooling. In extreme cases, in which the induced porosity is excessive, the rupturing may progress to one or more external surfaces. Either form of internal mechanically induced discontinuity may initiate in an area where inherited discontinuities are present.

Effect of Forging Material

Some types of forging flaws are unique to specific work metals, and may influence the choice of inspection method.

Steel Forgings. The most common surface flaws in steel forgings are seams, laps, and slivers. Other surface flaws include rolled-in scale, ferrite fingers, fins, overfills, and underfills. The most common internal flaws found in steel forgings are pipe, segregation, nonmetallic inclusions, and stringers.

Either magnetic particle or liquid penetrant inspection can be used for steel forgings, although magnetic particle inspection is usually preferred. Only liquid-penetrant inspection can be used for some stainless steel or nonferrous forgings. The selection of an inspection method depends on the size and shape of the forging and on whether the forging can be moved to the inspection station or the inspection equipment can be moved to the forging. For either inspection method, systems are available for inspecting forgings of almost unlimited size and weight (see articles on the specific inspection methods in this Volume). In most cases, magnetic particle inspection is less expensive and faster than liquid penetrant inspection.

Heat-Resistant Alloy Forgings. Most of the flaws found in forgings of heat-resistant alloys can be categorized as those related to scrap selection, melting, or primary conversion to bar or billet or those that occur during forging or heat treatment. Tramp elements such as lead or zinc have been present in the makeup of scrap charges at levels that have caused hot shortness and a degradation of hot-tensile ductility occurring near 370 °C (700 °F) of air-melted alloys.

No NDI method would reliably evaluate the presence or absence of possible tramp-element contamination, and composition checks or hot-tensile checks could be considered to be too random for complete assurance of the presence or absence of contamination. The positive corrective action is the use of a vacuum-remelted product.

Melt-related discontinuities, such as inclusions, pipe, unhealed center conditions, flakes, or voids, are the types of discontinuities that most frequently exist in heat-resistant alloy forgings. Ultrasonic inspection can detect and isolate these conditions when they exist. Segregated structures, unmelted electrodes, or portions of stringer rods are types of discontinuities that may sometimes be found in heat-resistant alloys.

Flakes (internal cracks) can be produced each time the material is heated and cooled to room temperature. The random orientation does not always present a properly oriented reflector for ultrasonic inspection, but in most cases flaking can be detected ultrasonically with a high degree of reliability.

Unmelted pieces of electrode or shelf conditions appear infrequently in vacuum-melted alloys. Either of these conditions can seriously degrade forgeability. Macroetching or another appropriate type of surface inspection of the machined forging or the billet is the most effective method of detecting unmelted electrodes or shelf conditions.

Seams are common to rolling practices, and are readily detected by visual, magnetic particle, or liquid penetrant inspection. Grinding cracks are caused by severe grinding, which promotes network-type cracking on the surface of the material being conditioned. The network-type cracking may be present immediately after grinding or may not occur until subsequent heating for further forging. Seams and grinding cracks will cause severe surface rupturing during forging. Center bursts occur during conversion to bar or billet if reduction rates are too severe or temperatures are incorrect; they are readily detected by ultrasonic inspection.

Ingot pipe, unhealed center conditions, or voids are melt-related discontinuities, but their occurrence in forgings is often a function of reduction ratio. The conversion practice must impart sufficient homogenization or healing to produce a product with sound center conditions. An example of an unsound condition that did not heal is shown in Fig. 7. Macroetching and ultrasonic inspection methods are the most widely used for identifying regions of unsoundness.

Fig. 7 Section through a heat-resistant alloy forging showing a central discontinuity that resulted from insufficient homogenization during conversion. Step machining was used to reveal the location of the rupture; original diameter is at right.

The nickel-base heat-resistant alloys are highly susceptible to surface contamination during heating for forging. Fuel oils containing sulfur will induce a grain-boundary attack, which will cause subsequent rupturing during forging. Paint or marking crayons with high levels of similar contaminants will cause similar areas of grain-boundary contamination. Surface contamination is not normally detected by NDI methods prior to heating and processing, but if present at a level high enough to cause contamination, rupturing during forging will occur that can be detected by visual inspection. If the contamination occurs after final forging, with no subsequent metal deformation, the contaminated areas will be apparent as areas of intergranular attack. Macroetching, followed by liquid penetrant inspection, should be used.

Advanced forging processes, such as isothermal and hot-die forging, and the increasing use of computer modeling have greatly reduced problems associated with heat-resistant alloy forgings. These developments are outlined in *Forming and Forging*, Volume 14 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*.

Nickel Alloy Forgings. The discontinuities that occur in nickel alloy forgings are generally of the same type as those found in heat-resistant alloy forgings; namely, cracks (external and internal), tears, seams, laps, coarse-grain wrinkles, inclusions, and pipe. Although all metals may be subject to thermal cracking during forging, the age-hardenable nickel alloys are more vulnerable than most other metals, thus requiring close temperature control during forging to avoid large temperature gradients.

Internal discontinuities in nickel alloy forgings can be located by ultrasonic inspection. Liquid penetrants are most often used to inspect for surface flaws; magnetic particles can be used if the alloy is sufficiently magnetic.

Aluminum Alloy Forgings. Common surface discontinuities in aluminum alloy forgings are laps, folds, chops, cracks, flow-throughs, and suck-ins (Fig. 8(a) and 8(b)). The generation of these discontinuities is associated with the forging operation, processing practices, or design. Cracks can also result from seams in the forging stock.

Fig. 8(a) Typical discontinuities found in aluminum alloy forgings. See text for discussion.

Fig. 8(b) Band of shrinkage cavities and internal cracks in an alloy 7075-T6 forging. The cracks developed from the cavities, which were produced during solidification of the ingot and which remained during forging because of inadequate cropping. Etched with Keller's reagent. 9×

The internal discontinuities that occur in aluminum alloy forgings are ruptures, cracks, inclusions, segregation, and occasionally porosity (Fig. 8(a) and 8(b)). Ruptures and cracks are associated with temperature control during preheating or forging or with excessive reduction during a single forging operation. Cracks can also occur in stock that has been excessively reduced in one operation. Inclusions, segregation, and porosity result from forging stock that contains these types of discontinuities.

The inspection of aluminum alloy forgings takes two forms: in-process inspection and final inspection. In-process inspection, using such techniques as statistical process control and/or statistical quality control, is used to determine if the product being manufactured meets critical characteristics and if the forging processes are under control. Final inspection, including mechanical property testing, is used to verify if the completed forging product conforms with all drawing and specification criteria. Typical final inspection procedures used for aluminum alloy forgings include dimensional checks, heat treatment verification, and nondestructive evaluation.

Dimensional Inspection. All final forgings are subjected to dimensional verification. For open-die forgings, final dimensional inspection may include verification of all required dimensions on each forging or the use of statistical sampling plans for groups or lots of forgings. For closed-die forgings, conformance of the die cavities to the drawing requirements, a critical element in dimensional control, is accomplished prior to placing the dies in service by using layout inspection of plaster or plastic casts of the cavities. With the availability of computer-aided design (CAD) data

bases on forgings, such layout inspections can be accomplished more expediently with computer-aided manufacturing (CAM) driven equipment, such as coordinate measuring machines or other automated inspection techniques. With verification of die cavity dimensions prior to use, final part dimensional inspection may be limited to verifying the critical dimension controlled by the process (such as die closure) and monitoring the changes in the die cavity. Further, with high-definition and precision aluminum forgings, CAD data bases and automated inspection equipment, such as coordinate measuring machines and two-dimensional fiber optics, can be used in many cases for actual part dimensional verification.

Heat Treatment Verification. Proper heat treatment of aluminum alloy forgings is verified by hardness measurements and, in the case of 7xxx-T7xxx alloys, by eddy current inspection. In addition to these inspections, mechanical property tests are conducted on forgings to verify conformance to specifications. Mechanical property tests vary from the destruction of forgings to tests of extensions and/or prolongations forged integrally with the parts.

Nondestructive Inspection. Aluminum alloy forgings are frequently subjected to nondestructive inspection to verify surface or internal quality. The surface finish of aluminum forgings after forging and caustic cleaning is generally good. A root mean square (rms) surface finish of 3.2 μm (125 $\mu\text{in.}$) or better is considered normal for forged and etched aluminum alloys; under closely controlled production conditions, surfaces smoother than 3.2 μm (125 $\mu\text{in.}$) rms can be obtained. Selection of NDI requirements depends on the final application of the forging. When required, satisfactory surface quality is verified by liquid penetrant, eddy current, and other techniques. Aluminum alloy forgings used in aerospace applications are frequently inspected for internal quality using ultrasonic inspection techniques.

Magnesium alloy forgings are subject to the same types of surface and internal discontinuities as aluminum alloy forgings. In addition, surface cracks are common in magnesium alloy forgings and are usually caused by insufficient control of the forging temperature.

Visual inspection and liquid penetrant inspection are used to detect surface discontinuities. Ultrasonic inspection is used to locate internal discontinuities.

Titanium Alloy Forgings. Discontinuities that are most likely to occur in titanium alloy forgings are usually carried over in the bar or billet. Typical discontinuities in titanium alloy forgings are α -stabilized voids, macrostructural defects, unsealed center conditions, clean voids, and forging imperfections.

Alpha-stabilized voids are among the most common discontinuities found in forgings of titanium alloys. Investigation and research have determined that voids surrounded by oxygen-stabilized α grains may be present in the ingot (Fig. 9). Because of the size of these voids and the coarse-grain nature of the ingot, they cannot be detected until the ingot has been suitably reduced in cross section and refined in structure. When the structure has been refined, the voids can be detected by ultrasonic inspection. Also, when the section is reduced sufficiently, radiographic inspection can be effectively used.

Fig. 9 Ti-8Al-Mo-1V, as forged. Ingot void (black), surrounded by a layer of oxygen-stabilized α (light). The remaining structure consists of elongated α grains in a dark matrix of transformed β . Etched with Kroll's reagent (ASTM 192). 25 \times

Alpha voids do not readily deform during forging, nor do they align with the flow pattern, as do typical inclusions in carbon or alloy steel. In most cases, α voids appear to be somewhat globular. Extremely small voids do not present an especially ideal target or reflector for ultrasonic energy. Attempts to correlate size with amplitude of indication obtained during ultrasonic inspections have not been completely reliable. For critical-application forgings, the material is most often inspected twice--once in the bar or billet form before forging and again after forging. Because forging further refines structure and reorients possible discontinuities in relation to the sound-entry surface, the forging operation probably enhances the possibility of detecting these discontinuities.

Macrodefects. Three principal defects are commonly found in macrosections of ingot, forged billet, or other semifinished product forms. These include high-aluminum defects (Type II defects), high-interstitial defects (Type I defects or low-density interstitial defects), and β flecks. High-aluminum defects are areas containing an abnormally high amount of aluminum. These are soft areas in the material (Fig. 10) and are also referred to as

α segregation. Defects referred to as β segregation are sometimes associated with α segregation. These are areas in which aluminum is depleted. The high-interstitial defects (Fig. 11) are normally high in oxygen and/or nitrogen, which stabilize the α phase. These defects are hard and brittle; they are normally associated with porosity, as illustrated in Fig. 9.

Fig. 10 Ti-6Al-4V α - β processed billet illustrating the macroscopic appearance of a high-aluminum defect. 1.25 \times

Fig. 11 Macrodefects in titanium billets. Left: Ti-6Al-4V α - β processed billet illustrating macroscopic appearance of a high-interstitial defect. Actual size. Right: at 100 \times . The high oxygen content results in a region of coarser and more brittle oxygen-stabilized α than observed in the bulk material.

Beta flecks are regions enriched in a β -stabilizing element due to segregation during ingot solidification. Figure 12 shows the macroscopic appearance of β flecks in a Ti-6Al-6V-2Sn forging billet.

Fig. 12 Ti-6Al-6V-2Sn α - β forged billet illustrating macroscopic appearance of β flecks that appear as dark spots. Etched with 8 mL HF, 10 mL HF, 82 mL H₂O, then 18 g/L (2.4 oz/gal.) of NH₄HF₂ in H₂O. Less than 1 ×

Unsealed center conditions are associated with insufficient ingot reduction. These are more prevalent in the larger stock sizes (>230 mm, or 9 in., in diameter) and are normally removed by adequate cropping at the mill. Clean voids describe a condition that can be associated with unsatisfactory sealing of porosity elsewhere in the ingot or through center porosity formed during ingot reduction.

Nondestructive Inspection. Ultrasonic inspection is the most definitive and practical method of inspecting titanium alloy forgings. Inspection techniques are normally tailored to the rejection level indicated in the specifications and to the physical condition of the material being inspected. Surface conditions usually must be ideal, grain size must be fine, and structural conditions must be controlled. Most airframe or similar static parts are inspected with equipment settings based on a No. 3 flat-bottom-hole standard. For the examination of critical rotating forgings for aircraft gas-turbine engines, it is not uncommon to inspect to the equivalent of a No. 1 flat-bottom-hole standard. Experience with these highly critical forgings, which in service rotate at high speed in the presence of extreme temperature and pressure, has indicated that small α voids can initiate cracks and have caused catastrophic failures.

For satisfactory ultrasonic inspection of forgings to these stringent requirements, special techniques and equipment are usually required. Specially designed ultrasonic electronic equipment is used with focused or otherwise unique transducers. Also required are an immersion tank with rotating devices, automatic small incremental indexing devices, and automatic alarms for signal level. Special reference blocks are required, along with the usual flat-bottom-hole reference blocks. The correct indexing increment must be established, the linear alignment of the ultrasonic unit must be verified, and calibration checks must be made. All information must be recorded and retained for future reference.

Nondestructive Inspection of Forgings

Visual Inspection

Despite the many sophisticated inspection methods available, unaided visual inspection is still important and is often the sole method of inspecting forgings used for common hardware items. Under proper lighting conditions, the trained eye can detect several types of surface imperfections, including certain laps, folds, and seams. Visual inspection is often used first, then questionable forgings are further examined by macroetching and inspection with macrophotography or some type of nondestructive method.

The only equipment necessary for visual inspection is a bench on which to place the forging and suitable cranes or hoists for forgings that are too heavy to lift by hand. Good and well-controlled lighting conditions are essential. Optical aids such as magnifying glasses that can magnify up to about ten diameters are often used to increase the effectiveness of visual inspection.

Nondestructive Inspection of Forgings

Magnetic Particle Inspection

Magnetic particle inspection is useful for detecting surface imperfections as well as certain subsurface imperfections that are within approximately 3 mm ($\frac{1}{8}$ in.) of the surfaces in forgings of steel, some grades of stainless steel, and other ferromagnetic metals. Magnetic particle inspection can be used with fluorescent particles and ultraviolet light. Detailed information is available in the article "Magnetic Particle Inspection" in this Volume.

The **advantages** of magnetic particle inspection include the following:

- Almost instant results can be obtained in locating surface and certain subsurface imperfections
- Equipment can be transported to the forging, or the forging can be transported to the inspection station, as dictated by the size and shape of forging
- Preparation of the forging is minimal, mainly involving the removal of surface contaminants that would prevent magnetization or inhibit particle mobility
- Routine inspection work can be effectively done by relatively unskilled labor properly trained in interpretation
- For forgings that are simple in configuration, and when justified by the quantity, magnetic particle inspection can be automated
- For some forgings, electronic sensing can be used, thus reducing the chances of human error and increasing inspection reliability
- Many forgings have sufficient retentivity to permit the use of multidirectional magnetization, thus permitting the inspection of indications in all orientations with a single preparation. Retentivity must be checked for the particular forging before a decision is made to use multidirectional magnetization
- The cost of magnetic particle inspection is generally lower than that for several other inspection methods in terms of investment in equipment, inspection materials, and inspection time

The limitations of the magnetic particle inspection of forgings are generally the same as for inspecting other workpieces and include the following:

- The method is applicable only to forgings made from ferromagnetic metals
- Because magnetic particle inspection is basically an aided visual inspection, under most circumstances, its effectiveness is subject to the visual acuity and judgment of the inspector
- Magnetic particle inspection is generally limited to detecting imperfections that are within about 3 mm ($\frac{1}{8}$ in.) of the surface of the forging
- Because the forging must be thoroughly magnetized, magnetic particle inspection is likely to be ineffective unless scale, grease, or other contaminants are removed from the forging. Such surface contaminants inhibit the mobility of the particles necessary to delineate the indications
- Following inspection, the forging usually must be demagnetized, depending mainly on the retentivity of the particular metal, subsequent shop operations, and end use

Detection of Surface Discontinuities. Magnetic particle inspection and liquid penetrant inspection are both widely used for detecting discontinuities in steel forgings, although the former is the more widely used. As described above and in the articles that deal with the specific inspection methods in this Volume, one advantage of using the magnetic particle technique is its ability to detect certain subsurface discontinuities that are not open to the surface. Subsurface discontinuities cannot be located with liquid penetrants. Also, some surface discontinuities may be so packed with scale that liquid penetrant techniques are marginal or infeasible. Therefore, in most cases, magnetic particle inspection is preferred to liquid penetrant inspection. Continuous magnetization is usually prescribed for inspecting steel forgings, because at the stage in which the forgings are inspected they are in an annealed or semiannealed condition and consequently have poor retentivity of magnetism.

Two inspection methods are available: dry powder and wet. Selection between the dry and the wet methods may sometimes be purely arbitrary, although it is usually based on the available equipment and the size of the forgings being inspected. The dry-powder method is used to a greater extent for large forgings. Similarly, selection between fluorescent and nonfluorescent particles may often be arbitrary, although the size of the forging can be a major factor, because if the fluorescent method is used the forging must usually be of such size and shape that it can be inspected under ultraviolet light, with white light substantially eliminated.

Many specific procedures have been established for in-plant use. The dry-powder and wet techniques adopted in one plant for the inspection of ferromagnetic metal forgings are described below.

Dry-Powder Technique. The contact method of magnetization was selected to inspect the ferromagnetic materials. Prods are used to pass direct current or rectified alternating current through the workpiece. The magnetic particles are

nontoxic, finely divided ferromagnetic material of high permeability and low retentivity, free from rust, grease, dirt, or other materials that may interfere with the proper functioning of the magnetic particles. The particles must also exhibit good visual contrast with the forging being inspected.

Inspection is by the continuous-current method; that is, the magnetizing current remains on during the period of time that the magnetic particles are being applied and also while the excess particles are being removed. Prods are spaced 150 to 200 mm (6 to 8 in.) apart, except where restricted by configuration. The magnetic field is induced in two directions, 90° apart. The current used is 4 to 5 A/mm (100 to 125 A/in.) of prod spacing and is kept on for a minimum of $\frac{1}{5}$ s.

Dry magnetic particles are applied uniformly to the surface, using a light dustlike technique. Excess particles are removed by a dry-air current of sufficient force to remove the excess particles without disturbing particles that show indications.

The nozzle is held obliquely about 35 to 50 mm ($1\frac{1}{2}$ to 2 in.) above the test area. Nozzle size and air pressure result in a pressure (measured by a manometer) of 25 to 40 mm (1.0 to 1.5 in.) of water at an axial distance of 25 mm (1 in.) from the nozzle and 7.5 to 15 mm (0.3 to 0.6 in.) of water at 50 mm (2 in.) from the nozzle.

A 100 mm (4 in.) grid pattern over the entire forging surface is normally used for evaluation (Fig. 13). The prods are placed 200 mm (8 in.) apart (Fig. 13), except where restricted by the shape of the forging, when using this grid pattern.

Fig. 13 Grid pattern and prod positions used in one plant for the magnetic particle inspection of forgings using prods and the dry-powder technique

Prods are placed on the surface to be tested in the proper position, as shown by position 1 in Fig. 13, and the current is turned on (4 to 5 A/mm, or 100 to 125 A/in., of prod spacing). The powder is applied, the excess particles are removed, and the current is turned off. Inspection is conducted during application of the powder and after removal of the excess particles.

The next step is to reposition the prods 90°, as indicated by position 2 in Fig. 13; the above procedure is then repeated. When the shape of the forging does not permit a full 90° rotation with the established prod spacing, the prod spacing can be changed, provided it is not less than 50 mm (2 in.) nor more than 200 mm (8 in.) between prods.

Wet Technique. The magnetic particles selected are nonfluorescent and suspended in a liquid vehicle. The magnetizing equipment is capable of inducing a magnetic flux of suitable intensity in the desired direction by both the circular and the longitudinal methods. Direct current from generators, storage batteries, or rectifiers is used to induce the magnetic flux. Circular magnetization is obtained by passing the current through the forging being examined or through a central conductor to induce the magnetic flux. Longitudinal magnetization is obtained by using a solenoid, coil, or magnet to induce the magnetic flux. The magnetic particles are nontoxic and exhibit good visual contrast. The viscosity of the suspension vehicle for the particles must be a maximum of 5×10^{-6} m²/s (5.0 centistokes) at any bath temperature used. The magnetic particles are limited to 28 to 40 g (1.0 to 1.4 oz) of solid per gallon of liquid vehicle.

The liquid used as a vehicle for the magnetic particles may be a petroleum distillate such as kerosene. Tap water with suitable rust inhibitors and wetting and antifoaming agents can be substituted for the petroleum distillate. The water should contain about 0.3% antifoam agent, 3.9% rust inhibitor, and 12.8% wetting agent.

Inspection is carried out by the continuous method. For this method, the magnetizing circuit is closed just before applying the suspension or just before removing the forging from the suspension. The circuit remains closed for approximately $\frac{1}{5}$ to $\frac{1}{2}$ s.

For circular magnetization, an ammeter is used to verify the presence of adequate field strength. For verifying adequate field strength in longitudinal magnetization, a field indicator is useful. Typical current levels utilized to provide an adequate field strength are 4 to 12 A/mm (100 to 300 A/in.) of diameter of the surface being examined, although current levels of up to 30 A/mm (750 A/in.) of diameter have been used.

The magnetizing force for longitudinal magnetization is 2000 to 4000 ampere-turns per 25 mm (1 in.) of diameter of the surface being examined. If both the inside and outside diameters of cylindrical parts are to be inspected, the larger diameter is used in establishing the current. If it is impractical to attain currents of the calculated magnitude, a magnetic field indicator is used to verify the adequacy of the magnetic field.

Suspensions must be tested daily or when they appear to have become discolored by oil or contaminated by lint. Common practice is to test the suspension at the beginning of each operating shift. The suspension test is conducted as follows:

- Let the pump motor run for several minutes to agitate a normal mixture of particles and vehicle
- Flow the bath mixture through the hose and nozzle for a few minutes to clear the hose
- Fill the centrifuge tube to the 100-mL line
- Place the centrifuge tube and stand in a location free from vibration
- Let the tube stand for 30 min for particles to settle out
- After 30 min, readings for settled particles should be 1.7 to 2.4 mL. If the reading is higher, add vehicle; if lower, add particle powder to the suspension

Example 1: Magnetic Particle Inspection of 1541 Steel Connecting Rods by the Multidirectional System.

Connecting rods for piston engines were manufactured from 1541 steel by forging in closed dies. Because connecting rods used in piston engines are subject to considerable stress, it is necessary to ensure the integrity of these parts, especially in heavy-duty applications, such as high-performance automobiles and trucks. Accordingly, fluorescent magnetic particle inspection of the forged connecting rod was done immediately after unwanted scale and dirt were removed by shotblasting. Bidirectional (longitudinal and transverse) magnetic fields were generated rapidly and sequentially by the use of a multidirectional magnetizing machine, as shown in Fig. 14. The use of this machine allowed for a single inspection to detect all discontinuities regardless of their orientation.

Fig. 14 Setup for the inspection of forged 1541 steel automotive connecting rods by the magnetic particle method using a multidirectional magnetizing system

The process of manufacturing connecting rods usually results in only longitudinally oriented flaws, but, transversely oriented flaws occasionally do occur. Hot tears along the trim line and metal folds or laps in the web area are of primary interest in the inspection. Worn tooling, overheating, and underheating of the forging blanks, as well as improper trimming, are the primary causes of these flaws.

Inspection Procedure. The inspection of these connecting rods utilized a multidirectional system, and the inspection procedure was as follows. Initially, the connecting rod was pneumatically clamped in the contact heads (Fig. 14) and then automatically flooded with a suspension of fluorescent magnetic particles. The magnetizing fields were induced while the suspension was draining from the part. Current settings for circular magnetization were 1000 A; for longitudinal magnetization, 4500 ampere-turns equivalent. The magnetizing current automatically switched back and forth, thus revealing any imperfections regardless of their orientation. Inspection of the forging was done under an ultraviolet light of no less than 2700 lx (250 ftc) at the surface of the forging. Following completion of inspection, the forging was demagnetized so that metal chips did not adhere to the surface during subsequent machining operations. The principal disadvantage of this inspection procedure was that the production rate was limited because the procedure was performed manually.

Example 2: Use of Electromagnetic, Ultrasonic, and Magnetic Particle Methods for the Inspection of Forged 1046 Steel Steering Knuckles.

Automobile steering knuckles similar to the forged 1046 steel knuckle shown in Fig. 15 are regarded as extremely high-integrity parts. At one plant, to provide the required degree of quality control, 100% of all steering knuckles were nondestructively inspected using three different techniques--electromagnetic comparison for hardness and ultrasonics for internal soundness at one location, followed by in-line fluorescent magnetic particle inspection.

Fig. 15 Steering knuckle, forged from 1046 steel, that was inspected by a combination of electromagnetic, ultrasonic, and magnetic particle methods. The setup for electromagnetic and ultrasonic inspection is shown. Dimensions given in inches

Inspection Procedures. Figure 15 shows the orientation of the steering knuckle during inspection with the electromagnetic test coil and ultrasonic transducer. Electromagnetic comparator coils were used to evaluate hardness in the bearing area; the ultrasonic 60° shear wave method was used to detect internal discontinuities in the spindle portion of the steering knuckle. The spindle of the knuckle was immersed in a dielectric oil to provide couplant for the ultrasonic inspection; a 5.0-MHz transducer was used. For electromagnetic inspection, a 60-Hz frequency was used for the hardness detection comparator. Electromagnetic and ultrasonic inspections were combined both for efficiency and compatibility of the two methods.

All steering knuckles were fluorescent magnetic particle inspected following the electromagnetic-ultrasonic inspection. This inspection was accomplished by magnetizing the steering knuckle between contact plates, flooding with the particle suspension, and viewing under an ultraviolet light having an intensity of 2700 lx (250 ftc) minimum. The steering knuckles were then transported by conveyor to a magnetizing coil for magnetizing in the other direction so that circumferentially oriented indications would be shown under a subsequent second ultraviolet light inspection. These

nondestructive tests resulted in the detection of both internal and external flaws as well as the detection of variations in hardness.

Nondestructive Inspection of Forgings

Liquid Penetrant Inspection

Liquid penetrant inspection is a versatile NDI process and is widely used for locating surface imperfections in all types of forgings, either ferrous or nonferrous, although it is more frequently used on nonferrous forgings. There is no limitation on the size or shape of a forging that can be liquid penetrant inspected.

Any of the three basic liquid penetrant systems (water-washable, postemulsifiable, and solvent-removable) can be used to inspect forgings. The product or product form is not a principal factor in the selection of a system. The fundamentals of the three systems, as well as the advantages and limitations of each for inspecting various products (including forgings), are presented in the article "Liquid Penetrant Inspection" in this Volume.

Advantages. Among the advantages of liquid penetrant inspection of forgings are the following:

- There are no limitations on metal composition or heat-treated condition
- There are no limitations imposed on the size or shape of the forging that can be inspected
- Liquid penetrant inspection can be done with relatively simple equipment
- Training requirements for inspectors are minimal
- Inspection can be performed at any stage of manufacture
- Liquid penetrant materials can be taken to the forgings or the forgings taken to the inspection station, depending on the size and shape of the forgings

The limitations of the liquid penetrant inspection of forgings are basically the same as those for the inspection of other workpieces. The characteristics of the surface of a forging sometimes impose specific limitations. The most important general limitations are:

- Liquid penetrant inspection is restricted to detecting discontinuities that are open to the surface
- Liquid penetrant inspection is basically a visual aid; therefore, results depend greatly on the visual acuity and judgment of the inspector
- Satisfactory inspection results require that the surface of the forging be thoroughly cleaned before inspection. The presence of surface scale can cause inaccurate readouts. If the surface of the forging is excessively scaled, it should be pickled or grit-blasted, preferably pickled. The forgings should also be cleaned to remove surface contaminants, such as grease and oil
- Liquid penetrant inspection is slower than magnetic particle inspection

Nondestructive Inspection of Forgings

Liquid Penetrant Detection of Flaws in Steel Forgings

Factors affecting the selection of a special penetrant system for inspecting steel forgings include available equipment; size, shape, and surface conditions of the forgings; degree of sensitivity required; whether or not the entire forging requires inspection; and cost. Regardless of which system is used, the degree of success achieved depends greatly on the surface conditions of the forging. Rough, scaly surfaces are likely to result in either false indications or obscuring of meaningful flaws. Pickled surfaces are preferred. Abrasive blasting is usually satisfactory for cleaning forging surfaces,

although overblasting must be avoided or some flaws may be tightly closed and prevent the penetrant from entering. The postemulsifiable and solvent-removable liquid penetrant systems are most often used to inspect steel forgings.

The postemulsifiable system is generally preferred to the water-washable system for forgings because of its greater sensitivity. Either the fluorescent-penetrant or the visible-dye technique can be used. Selection depends largely on whether ultraviolet-light inspection can be used. For forgings of a size and shape that can be immersed in tanks and inspected in a booth, the fluorescent technique is usually preferred.

The solvent-removable system is especially well adapted to applications in which only a portion of the forging requires inspection. Equipment for this system can be minimal and completely portable or may involve more elaborate systems used on a production basis, as described in the following examples.

Example 3: Solvent-Removable Liquid Penetrant Inspection of Type 316 Stainless Steel Forged Valve Bodies.

Figure 16 illustrates the equipment layout used for the liquid penetrant inspection of 150 and 200 mm (6 and 8 in.) type 316 stainless steel forged valve bodies by the solvent-removable visible-dye system. This same equipment layout was also used for many other sizes and types of forgings requiring liquid penetrant inspection, such as the bonnet forgings described in the next example. The roller conveyor shown in Fig. 16 provided easy handling of relatively large forgings and, at the same time, allowed for the variations in time cycles that were compatible with the various sizes and shapes of forgings.

Fig. 16 Equipment layout for the liquid penetrant inspection of type 316 stainless steel forged valve bodies and bonnet forgings by the solvent-removable visible-dye system

Inspection Procedure. The processing cycle that proved satisfactory for inspection of the forged valve bodies was as follows:

- Preclean by gritblasting, followed by a light etch in a 30% HNO_3 , 10% HF , and 60% H_2O (by volume) acid solution. Forgings were also ground and polished as required so that the surface roughness was 6 μm (250 $\mu\text{in.}$) maximum
- Vapor degrease (wiping with 1,1,1-trichloroethane is an acceptable alternative)
- Apply solvent-removable visible-dye penetrant with a spray gun at a pressure of approximately 140 kPa (20 psig). Workpiece temperature should be kept within the temperature range of 10 to 40 $^\circ\text{C}$ (50 to 100 $^\circ\text{F}$)

°F)

- Allow dwell time (penetration) of 15 to 20 min
- Rough wipe with lint-free cloth or absorbent paper
- Finish wipe with cloth or absorbent paper moistened with solvent remover (same group as the penetrant)
- Air dry for 5 to 10 min
- Apply nonaqueous developer, using a spray gun or pressurized spray cans, and allow drying time of 7 to 30 min prior to inspection
- Inspect in a booth using adequate light intensity, although at a level that will avoid producing a glare from the white surface

Acceptable workpieces were then cleaned by flushing with tap water, wiping with 1,1,1-trichloroethane, and air drying. They were then stamped and moved to the next processing operation.

Forgings that failed to meet acceptance standards were marked by encircling the flaw with a crayonlike marker that did not contaminate the surface. The flaws were then ground and polished, and the forging was reinspected in accordance with the above procedure.

Example 4: Solvent-Removable Liquid Penetrant Inspection of Type 316 Stainless Steel Bonnet Forgings.

The solvent-removable visible-dye system of liquid penetrant inspection and the equipment shown in Fig. 16 were used to detect surface imperfections in 340 kg (750 lb) type 316 stainless steel bonnet forgings (Fig. 17).

Fig. 17 Bonnet forging of type 316 stainless steel that was liquid penetrant inspected for surface flaws by the solvent-removable visible-dye system. Dimensions given in inches

Precleaning. Forged bonnets were delivered to the penetrant inspection operation in the machined condition. Machined workpieces were lightly etched in a 30% HNO₃, 10% HF, and 60% H₂O (by volume) acid solution and thoroughly water rinsed (spray or immersion) to remove all traces of acid. Workpieces were then swabbed with a 5% ammonia solution and subsequently rerinsed in water (spray or immersion). They were then allowed to dry at room temperature. Immediately preceding application of the penetrant, the etched forgings were pre-cleaned with 1,1,1-trichloroethane and allowed to dry at room temperature for at least 5 min.

Inspection Procedure. The forgings were inspected in accordance with the following procedure:

- Apply solvent-removable visible-dye penetrant (group 1, MIL-I-25135) to the surfaces of the workpieces with a spray gun attached to the shop air line (brushing is an acceptable alternative). The penetrant need not be applied to the inside bore surfaces (as indicated in Fig. 17), because these surfaces are to be machined and subsequently inspected. Temperature of the workpiece for this operation as well as for subsequent operations is maintained within 15 to 50 °C (60 to 120 °F)
- Allow dwell time of 15 to 25 min
- Remove excess penetrant, using a solvent remover of the same family as the penetrant, by wiping with lint-free cloths or absorbent paper
- Final wipe with lint-free cloth or absorbent paper dampened slightly with solvent remover
- Dry at room temperature for 5 to 10 min
- Apply nonaqueous developer with a spray gun, pressurized spray can, or airbrush. Agitate developer periodically during application. Apply with short dusting strokes so that a uniform but thin layer is applied
- Perform inspection no sooner than 7 min and no later than 30 min following developer application
- Inspect, using adequate white light, but at a level that will avoid glare
- Clean inspected forgings by wiping with clean cloths moistened with 1,1,1-trichloroethane

Indications were evaluated in accordance with specifications listed as follows:

- *Linear indications:* None longer than 4.2 mm ($\frac{1}{6}$ in.)
- *Rounded indications:* None greater than 4.8 mm ($\frac{3}{16}$ in.) in diameter
- *Linearly disposed rounded indications:* Four or more in line separated by 1.6 mm ($\frac{1}{16}$ in.) or less, measured edge to edge, are evaluated as linear indications
- *Multiple indications:* No more than ten within any area of 40 cm² (6 in.²) and whose major dimension is no more than 150 mm (6 in.)

Repair and Reinspection. Forgings containing flaws in excess of the above acceptance standards were repaired by grinding or polishing, provided these operations did not impair dimensional requirements. Forgings that were repaired by grinding or polishing were subject to reinspection using the technique and acceptance standards outlined above.

Nondestructive Inspection of Forgings

Liquid Penetrant Detection of Flaws in Heat-Resistant Alloy Forgings

Because most heat-resistant alloy forgings are nonmagnetic, the use of magnetic particle inspection for detecting surface flaws cannot be considered. Liquid penetrants are extensively used for inspecting the surfaces of high-integrity forgings. Critical forgings such as these require close quality control surveillance. Following production penetrant inspection using group VI fluorescent penetrant, it is desirable to conduct quality control overchecks on samples selected from previously inspected batches. These overchecks are performed using highly sensitive, high-resolution penetrants, as described in the following examples.

Example 5: Routing Liquid Penetrant Inspection of Jet-Engine Cooling Plates Forged From René 95.

Cooling plates (Fig. 18) used in the rear of several jet engines were forged from René 95, which is a nickel-base heat-resistant alloy.

Fig. 18 Forged René 95 cooling plate for a jet engine that was first inspected by the postemulsifiable fluorescent penetrant system and then reinspected by a high-resolution penetrant after being accepted. Dimensions given in inches

Inspection Procedures. Forgings of this type were inspected in accordance with type 1, method B (MIL-I-6866), which is a postemulsifiable fluorescent penetrant inspection using group VI (MIL-I-25135) penetrants, emulsifiers, and dry developers. The following procedure was used:

- Clean machined forgings with solvent (1,1,1-trichloroethane) by immersion, swabbing, or wiping
- Lightly etch each forging with an acid mixture of 80% HCl, 13% HNO₃, and 7% HF (by volume)
- Rinse (immerse or spray) in tap water to remove all traces of acid
- Air dry prior to penetrant application. Inspect visually for adequacy of etch and to ascertain that forgings are dry
- Using a basket-type container, immerse several forgings at a time into group VI (MIL-I-25135) fluorescent penetrant. Allow to soak in penetrant or rest on drain table for at least 30 min
- Immerse container in emulsifier (group VI, MIL-I-25135), or hose on emulsifier, taking care to completely cover each forging completely. Allow emulsification time of $2\frac{1}{2}$ min maximum
- Wash off excessive emulsified penetrant, using water at 40 °C (100 °F) maximum. Forgings can be immersed in agitated water wash or can be cleaned by a water spray located at the wash station
- Verify adequacy of removal of excess penetrant by use of ultraviolet light located at the wash station
- Dry in oven at 60 to 80 °C (140 to 180 °F) for 7 min maximum
- Visually inspect forging for adequacy of drying cycle
- Apply dry developer over entire surface of forging, using compressed air with a dry developer-applicator hose
- Allow development time of 10 to 15 min

Following development, the forgings were inspected in a darkened booth using a portable ultraviolet light (intensity: 1060 $\mu\text{W}/\text{cm}^2$, or 6840 $\mu\text{W}/\text{in.}^2$). Unacceptable indications were recorded; acceptance standards were as follows:

- No linear indications are permitted
- Scattered nonlinear indications are permitted if they are not visible at one diameter in white light (1075 1x, or 100 ftc, at surface subject to inspection), if they are separated by at least 3 mm ($\frac{1}{8}$ in.), and if there are no more than ten in any 25 mm (1 in.) diam area

All rejected forgings were scrapped or salvaged. Forgings that were salvaged were subject to reinspection in accordance with the above acceptance standards. Following inspection, the forgings were cleaned by solvent or water (spray or immersion) to remove retained developer. They were then dried at room temperature; a warm air blast was used to speed up the drying process.

Example 6: Quality Assurance Liquid Penetrant Inspection of Jet-Engine Cooling Plates Forged From René 95.

Because of the critical application for the forged jet-engine cooling plate described in Example 5 and illustrated in Fig. 18, and because of the type of flaws expected (very tight forging cracks at the periphery and excessive porosity), sample forgings were periodically selected at random from lots that had been accepted after being inspected by the procedure described in Example 5. The sample forgings were subjected to liquid penetrant inspection using a commercially available high-resolution fluorescent penetrant to evaluate the adequacy of each cycle used in the production penetrant inspection described in Example 5. In particular, the high-resolution penetrant was used to determine the effectiveness of salvage grinding and polishing operations utilized to remove unacceptable indications detected in the original inspection. It is important to recognize that the high-resolution penetrants are not normally adaptable to production liquid penetrant inspection. The following procedure was employed when conducting the quality assurance inspection:

- Thoroughly clean the surface of the forging, using high-resolution precleaner. When necessary, before precleaning, lightly etch with an 80% HCl, 13% HNO₃, and 7% HF (by volume) acid solution; rinse; and dry. Allow precleaner to dry for 4 to 5 min
- Apply high-resolution fluorescent penetrant over entire surface of the forging, using a fine brush or the dauber attached to the cap of the can containing the penetrant. Allow penetrant to dry completely (approximate drying time, 1 min)
- Soak a piece of cheesecloth or equivalent material with high-resolution penetrant remover and remove the dried penetrant from the surface of the forging, using a circular motion. The penetrant remover will liquefy excess surface penetrant. Remove all traces of excess penetrant by scrubbing with a clean, lint-free cloth under a flood of tap water at room temperature. Finally, wipe surfaces with a clean, lint-free cloth that has been dampened with tap water at room temperature
- Allow surface to dry thoroughly. Drying may be aided by a blast of clean air or by means of a fan
- Apply nonaqueous developer from agitated spray can, in light, uniform dusting strokes. Hold can approximately 150 to 250 mm (6 to 10 in.) from the surface of the forging
- Allow a minimum of 10 min to elapse before inspection and evaluation of indications. Evaluate indications under ultraviolet light (intensity: 1060 $\mu\text{W}/\text{cm}^2$, or 6840 $\mu\text{W}/\text{in.}^2$) in a darkened inspection booth. Acceptance standards are the same as those listed in Example 5
- Postclean, using either the high-resolution precleaner or a water wash, and then dry at room temperature

Flaws in excess of acceptance standards detected with the high-resolution penetrants determined the disposition of the lot or modifications to the production penetrant cycles and appropriate action taken.

Nondestructive Inspection of Forgings

Ultrasonic Inspection

Ultrasonic inspection is used to detect both large and small internal flaws in forgings. Detailed information on the fundamentals of this method can be found in the article "Ultrasonic Inspection" in this Volume.

Forgings, by their nature, are amenable to ultrasonic inspection. Both longitudinal or shear wave (straight or angle beam) techniques are utilized. The size, orientation, location, and distribution of flaws influence the selection of technique and the inspection results. Consider, for example, Fig. 19, which shows the influence of flaw orientation on signal response. There are, however, some definite limitations. All ultrasonic systems currently in use generate sound electrically and transmit the energy through a transducer to the forging. Because the relationship of sound transmitted to sound received is a factor in the inspectability of a forging, particular attention must be given to the surface condition of the forging. Although techniques and couplants can enhance the energy transmission from the transducer to the forging, as-forged surfaces impair the effectiveness of ultrasonic inspection. Near-surface flaws are most difficult to detect, and a dead zone* at the entry surface often interferes. Because of the difficulty involved in detecting surface flaws by ultrasonic inspection, another method, such as magnetic particle or liquid penetrant inspection, is often used in conjunction with ultrasonic inspection to inspect high-integrity forgings thoroughly.

Fig. 19 Comparisons of discontinuities at normal orientation versus radial orientation. (a) Discontinuity normal to sound energy, almost total reflection of energy back toward transducer. (b) Discontinuity at 0° with respect to 45° sound energy path, almost no energy reflected back toward transducer

Complex shapes are difficult to inspect ultrasonically because of the problems associated with sound-entry angle. Most ultrasonic inspection of forgings uses techniques that send waves into the forging perpendicular to the surface. Radii, fillets, and similar configurations must receive special treatment if all areas of the forging must be inspected. The special treatment involves the use of a standoff that has an end contoured to fit the inspection surface or the use of a small-diameter or focused transducer.

Application. In certain cases, where the end use of a forging is considered critical, ultrasonic inspection is used to inspect the wrought material before it is worked. Surface or internal flaws that are not detected before a billet is forged may not be detected in the final forging and will therefore be present in the finished part. Ultrasonic inspection is often used as part of a completely diagnostic inspection of a forging from newly designed dies, where use of the finished part does not warrant inspection of every part.

Quality control measures often include the ultrasonic inspection of random samples from a particular forging. This provides the necessary assurance that the process is under control and that variables affecting internal quality have not been inadvertently introduced.

Ultrasonic inspection is often used in the further evaluation of flaws detected by other nondestructive methods. This reduces the possibility that a particular forging will be unsuitable for its intended service.

Ultrasonic inspection can be used on every forging to validate its integrity for extremely rigorous requirements. This applies in particular to forgings for nuclear and aerospace applications, where rigid standards of acceptance have been established. Standards and criteria have been set up to detect material inclusions, internal voids, laminations, and other conditions. In addition, the inspection of every forging by ultrasonics has been effective in detecting excessive grain size and other structural conditions.

Ultrasonic inspection is often used to qualify a particular lot of forgings that has been subjected to certain variations in approved processing procedures. A notable instance is the use of ultrasonics to determine the presence of thermal flakes or in locating quench cracks.

Note cited in this section

- * The term dead zone refers to the depth below the entry surface where any echoes from flaws cannot be detected because they are masked by the trailing edge of the transmitted pulse. The dead zone depends on

sound velocity, test frequency, and pulse length and is different for different combinations of test metal, transducer, and test instrument.

Nondestructive Inspection of Forgings

Basic Procedures for Ultrasonic Inspection

Many specific procedures have been developed for the inspection of forgings by ultrasonics. The basic procedures described here are based on those developed for use in a specific plant.

Forgings of regular (symmetrical) shape are ultrasonically inspected at final inspection (prior to shipment). If possible, the entire forging is ultrasonically inspected.

Irregularly shaped forgings, which have a configuration that precludes complete inspection prior to shipment, are ultrasonically examined at the latest stage of processing that will permit examination of the entire forging (preliminary inspection). These complex shapes are then reexamined to the extent practical before shipping (final inspection). To ensure complete inspection coverage of the forging, the transducer is indexed with at least 15% overlap with each pass. The rate of scanning does not exceed 150 mm/s (6 in./s).

The surface roughness of forgings from which ultrasonic examination is conducted should be no greater than 6 μm (250 $\mu\text{in.}$), unless otherwise specified. The forging surfaces should also be free of extraneous material, such as loose scale, paint, dirt, or other contaminants.

Equipment

An ultrasonic, pulsed, reflection-type instrument is used to inspect forgings. The instrument is capable of operating at three or more frequencies; for example, 1.0, 2.25, and 5.0 MHz. The instrument provides a linear presentation (within $\pm 5\%$) to approximately 75% of the screen height or a minimum of 40 mm ($1\frac{1}{2}$ in.). Signal attenuators and calibrated gain control, if used, are accurate over the range used to $\pm 10\%$ of the nominal attenuation ratio. Forgings are examined by the longitudinal wave technique at 2.25 MHz unless adequate penetration cannot be obtained, in which case the inspection is conducted at 1.0 MHz.

Longitudinal Wave Ultrasonic Inspection

Where possible, all forgings are scanned in two directions perpendicular to each other. Disk (pancake) forgings are examined axially from at least one end face and radially from the circumference, whenever practical. Ring forgings are examined radially from at least the outside surface and axially from at least one end face.

Cylindrical forgings are examined radially from the circumference. The axial examination of cylindrical forgings can be conducted when practical, using the back-reflection method of longitudinal wave inspection.

Back-Reflection Method. Longitudinal wave inspection by back reflection is often performed with a 2.25-MHz transducer. A higher or lower frequency can be used, when necessary, to obtain a meaningful inspection result.

The sensitivity for longitudinal wave calibration is established by adjusting the instrument controls to obtain a 40 mm ($1\frac{1}{2}$ in.) back-reflection height from the opposite side of the forging over an area free of indications (this level corresponds to approximately 75% of the useful screen height of the instrument). Calibration must be reestablished for each change of thickness greater than 10%. The calibration level and minimum-back-reflection requirements as outlined in this section apply to areas with parallel surfaces.

Routine scanning is done at the calibration gain level. When specified, the instrument gain level is increased to at least two times the calibration gain level. Flaw amplitudes and back-reflection reduction are evaluated with the gain setting at

the calibration level of 40 mm ($1\frac{1}{2}$ in.) back-reflection height in an indication-free area as close as practical to the area of indications.

All areas of the forging are examined with sufficient gain to provide a minimum back-reflection amplitude of 40 mm ($1\frac{1}{2}$ in.), except for areas where reduction of the back reflection is associated with ultrasonic indications.

Recording of indications detected by back-reflection method is done as follows:

- Any indication having an amplitude that equals or exceeds 10% of the calibration back-reflection level is reported in increments of 10
- Any traveling indication equal to or exceeding 5% of the calibration back reflection is recorded. Traveling indications are defined as indications whose leading edge moves a distance equivalent to 25 mm (1 in.) or more of metal depth with movement of the transducer over the surface of the forging. Any cluster of indications equal to or exceeding 5% of the calibration back reflection is recorded. A cluster of indications is defined as five or more indications located in a volume representing a 50 mm (2 in.) or smaller cube in the forging
- Any continuous indication equal to or exceeding 5% of the calibration back reflection is recorded. A continuous indication is defined as an indication that can be held on the same plane over a square area whose sides are greater than twice the diameter of the search unit
- Any reduction in back reflection (associated with a discontinuity indication) exceeding 20% of the calibration back reflection, measured in increments of 10%, is recorded

Distance-Amplitude-Correction (DAC) Curve Method. The following refers to the primary test direction, which is the radial direction for hollow and shaft-type forgings and the axial direction for upset disk-type forgings. Test sensitivity is established with reference flat-bottom-hole standards machined into either the forging itself or separate reference blocks. If separate reference blocks are used for instrument calibration, they should be of material having an attenuation coefficient within $\pm 25\%$ of forged production material. A DAC curve is established for longitudinal wave inspection of the forging in the primary test direction through the use of reference blocks of various thicknesses and hole sizes, as explained in the article "Ultrasonic Inspection" in this Volume. The size of the flat-bottom hole and the metal distance from entry surface to the hole bottom depend on the maximum machined thickness in the primary test direction at the time of initial ultrasonic inspection.

The following method is used to prove that the calibration blocks have attenuation characteristics within 25% of the production forging. An acoustic-decay pattern (the initial three back reflections) is determined for the calibration-block material while that material is still part of a larger section, so that there is no side-effect cancellation or reinforcement on the exponential decay pattern. An acoustic-decay pattern is also determined for the production forging at the midlength, using the same type of instrument and transducer as used for determining the acoustic-decay pattern of the calibration-block material. The amplitude of the first back reflection should be the same for both tests and within the vertical linearity of the instrument. The calibration-block material, which is fabricated in accordance with either ASTM E 428 or E 127, is considered compatible with the production forging if the sum of the amplitudes of three successive back reflections from the production forging is within 25% of the sum of the amplitudes of three successive back reflections from the calibration-block material or if the slope of the plotted back-reflection amplitudes of the calibration-block material is within 25% of the slope of the plotted back-reflection amplitudes of the production forging at the same sound-travel distance.

Recording of indications detected by the DAC-curve method is determined by the types and magnitudes of indications. Those recorded are any indication whose amplitude equals or exceeds 100% of the established DAC curve; traveling, clustered or continuous indications (as defined above) that have amplitudes equal to or greater than 50% of the DAC curve; and any reduction in back reflection (associated with a discontinuity indication) exceeding 20% of the calibration back reflection, measured in increments of 10%.

Calibration: Primary Test Direction. At the time of initial inspection, the areas of greatest and least acoustical penetrability are determined by scanning selected passes, which are representative of the forging cross section, at a fixed instrument gain level. The amplitude of the first back reflection is monitored during these scans to determine the areas of greatest and least penetrability.

The amplitude of the reflection from the flat-bottom hole in the longest calibration block is set at 13 mm (0.5 in.) sweep to peak, and the other points of the DAC curve are obtained at this gain setting. This curve can be marked on the face of the screen or plotted on graph paper. This is the fixed DAC curve that will be used to evaluate the indications. Any portion of the DAC curve above the vertical linearity limits of the instrument is brought on screen with the attenuator for evaluation of the indications in this area.

After establishing the fixed DAC curve, the amplitude of the back reflection over the area of greatest acoustical penetrability is determined at this instrument gain level. The transducer is then coupled to the forging over the area of least penetrability, and the gain setting of the instrument is increased to bring the back reflection to the same amplitude as the amplitude obtained over the area of greatest acoustical penetrability (a minimum of 40 mm, or $1\frac{1}{2}$ in., sweep to peak). For scanning, the instrument gain level is increased a minimum of twice the final gain setting.

Any indication, detected while scanning, whose amplitude equals or exceeds the reporting level is evaluated. This evaluation is conducted by readjusting the back reflection in a discontinuity-free area of the forging as close as practical to the area of indication to equal the same height of back reflection obtained in the area of greatest acoustic penetrability when the DAC curve was established. The search unit is repositioned over the area of the indication, and the evaluation to the DAC curve is made.

Back-reflection reduction is evaluated by adjusting the first back reflection to the maximum back reflection within the vertical linearity limits of the instrument in a discontinuity-free area of the forging as close as practical to the area of the indication to be evaluated. The search unit is repositioned over the area containing the indication, and the amplitude is recorded.

For contoured forgings at final inspection, ultrasonic inspection in the primary test direction is performed using a DAC curve established from the same reference blocks used for preliminary inspection. The last point of the curve is 13 mm (0.5 in.) sweep to peak, and the other points of the DAC curve are obtained at that gain setting. This is the fixed DAC curve that will be used to evaluate any indications. Compensation for the areas of greatest and least penetrability does not apply at final inspection with a contoured forging.

Calibration: Secondary Test Direction. The secondary test direction is approximately at 90° to the primary direction. The transducer is coupled to the face of the forging, and the amplitude of the first back reflection is set within the vertical linearity limit of the instrument (minimum 40 mm, or $1\frac{1}{2}$ in., sweep to peak). The DAC curve is established at this gain setting, using the same blocks that were used for the longitudinal wave inspection in the primary test direction. The last point of the DAC curve is extended parallel to the sweep line to midlength plus 25 mm (1 in.). Any indications will be evaluated against this DAC curve. When the configuration of the forging at final inspection due to contour machining prevents ultrasonic examination in the axial direction to midlength plus 25 mm (1 in.), the DAC curve will be extended parallel to the sweep line to the deepest location, wherever possible, for evaluation of the indications.

Shear Wave Ultrasonic Inspection

Shear wave inspection is performed from the circumference of rings and hollow forgings that have axial length greater than 50 mm (2 in.) and a ratio of outside to inside diameters of less than 2:1. A 1.0-MHz, 45° angle-beam search unit is used when shear wave inspecting forgings having a ratio of outside to inside diameters of less than 1.4:1. Forgings with a ratio of outside to inside diameters of 1.4:1 or greater, but less than 2:1, will be shear wave tested at a beam angle of less than 45°. Shear wave inspection is performed by scanning in both circumferential directions (clockwise and counterclockwise) along the periphery of the forging.

Inside diameter and outside diameter calibration notches are cut axially in the surface of the forging or a similar testpiece (preferably, excess metal or test metal). The sides of the notches should be smooth and parallel to the axis of the forging.

The calibration notches are 25 mm (1 in.) long, V-shaped or rectangular, with a width not exceeding twice the depth. These notches should have a depth of 3% of the maximum section thickness (based on thickness at initial ultrasonic inspection) or 6 mm ($\frac{1}{4}$ in.), whichever is smaller. If at final inspection it is necessary to place the calibration notches in the forging, these will have to be weld repaired.

The sensitivity for angle-beam inspection of the forging is established by adjusting the instrument controls to obtain a minimum 13 mm (0.5 in.) sweep-to-peak indication from the outside diameter calibration notch. The response from the inside diameter calibration notch is then obtained at this sensitivity level. The peaks of the indications from the inside diameter and outside diameter notches are connected to establish a reference line. Gain is increased two times for scanning. For contoured forgings at final inspection, the inspection is conducted to the extent that contour permits a meaningful examination.

Recalibration

Any realignment of the transducer with respect to the material or any change in the search unit, couplant, or instrument settings from that used for calibration necessitates recalibration. A calibration check is performed at least once every 8-h shift. If a 15% or greater decrease in the sensitivity level is observed during a calibration check, then the required calibration is reestablished, and all material examined in the preceding calibration period is reexamined.

Nondestructive Inspection of Forgings

Ultrasonic Inspection of Specific Forgings**

The procedure used for the ultrasonic inspection of a given forging depends greatly on the size and shape of the forging, and sometimes more importantly on the degree of inspection that is required. For example, a dome-shaped forging such as the low-alloy steel forging shown in Fig. 20 has a symmetrical shape that readily permits inspection by either the immersion or the contact ultrasonic method with no great problems other than the handling equipment needed.

Fig. 20 Symmetrical, dome-shaped forging that was ultrasonically inspected by the longitudinal wave technique on the inside and outside of the dome and on the ends, and by the circumferential shear technique on the outside of the dome and the neck portion. Dimensions given in inches

The forging illustrated in Fig. 20 was inspected by using the longitudinal wave technique on the inside diameter, outside diameter, and ends of the forging, plus the circumferential shear technique on the outside diameter. In addition, circumferential shear was conducted on the outside diameter of the neck portion of the forging.

The landing-gear forging illustrated in Fig. 21 has a more intricate shape and is large, which makes it more difficult to inspect. For forgings such as this, the best procedure is thorough inspection of the billets prior to forging. A common practice is to ultrasonically inspect the billet material to an agreed-on specification. This minimizes the amount of inspection required after forging. A forging such as the one shown in Fig. 21 would be ultrasonically inspected by immersion, longitudinal wave, hand-scan techniques in all areas where the shape permits. The following examples describe procedures used for the ultrasonic inspection of a variety of steel and aluminum alloy forgings.

Fig. 21 Landing-gear forging typical of complex forgings that are preferably ultrasonically inspected in billet form because the intricate forged shape prevents thorough ultrasonic inspection

Example 7: Ultrasonic Inspection of Forged Medium-Carbon Steel Axle Shafts for the Detection of Chevrons and Burning.

Automotive rear-axle shafts (Fig. 22) are made from medium-carbon steels by first forging in closed dies to form the hub end and then by cold extrusion to form the shaft section. Cold-extruded rear-axle drive shafts are prone to develop serious internal flaws known as chevrons or cup-cone ruptures. Chevrons are internal ruptures that may or may not extend to the surface of the extruded stock (most often they do not extend to the surface). There may be any number of chevrons produced during the extrusion of a single axle shaft. Therefore, it is necessary to inspect the entire length of each shaft.

Fig. 22 Setup and operating essentials for the ultrasonic inspection of the shaft portion of a forged medium-carbon steel axle shaft

Inspection Procedure. To perform a 100% ultrasonic inspection of these axle shafts in a plant where production was 2 to 3 million units annually, an automated system was used. The test station was supplied by a conveyor.

Figure 22 illustrates the position of the axle shaft when the ultrasonic test was performed. A transducer holder, with a fixed angle fabricated of hardened tool steel with no adjustment, coupled the ultrasound from the transducer to the shaft end. A detailed view of the transducer holder and V-block is shown in detail B in Fig. 22. Transducers with a frequency of 1.6 to 2.25 MHz were used to perform the ultrasonic inspection. The transducer incident angle was approximately 20°, which yielded a 45° shear wave generated within the shaft. This permitted the detection of internal flaws. The oscilloscope display in detail A in Fig. 22 illustrates the interaction of an ultrasonic beam with a chevron. Two electronic gates were utilized to monitor two separate areas of the shaft, the area from where the sound enters the shaft to

approximately 150 mm (6 in.) from the end of the flange. This was a positive gate, commonly called the chevron channel. The second gate was positioned to monitor the back-reflection signal and was a negative gate.

The acceptance of any axle shaft required a strong back reflection with no signal in the chevron channel gate. In addition to detecting chevrons, this inspection procedure detected the results of any burning that had occurred during heating. A burned forging attenuated the back reflection and caused the forging to be rejected.

Example 8: Ultrasonic Inspection of a 1.7 m (68 in.) Diam 8822 Steel Billet and the Ring Into Which It Was Rolled.

The large steel ring shown in Fig. 23 was produced for a nuclear application from a 1.7 in (68 in.) diam billet of 8822 steel. The large billet was first forged into a doughnut preform in a large press, then formed into the ring by ring rolling.

Fig. 23 Large rolled ring that was ultrasonically inspected as a 1.7 m (68 in.) diam billet and as a rolled ring

A ring of this type requires a high degree of integrity; therefore, inspections were performed at various stages of manufacture. Routine ultrasonic inspection of the billet revealed a gross center condition in approximately 67% of the length. Inspection was performed from the outside diameter and end faces to the maximum extent possible. On billets of this size, however, the surface condition and the lack of refinement of the internal structure have an adverse effect on the ability to perform a thorough inspection by ultrasonics.

When the billet was preformed into the doughnut shape, the portion that had been the center of the billet was removed. The doughnut was then ring rolled into a large ring having a wall 460 mm (18 in.) thick (Fig. 23). It was hoped that the area indicated as defective in the billet stage would have been removed, but because it was uncertain whether all of the defective area had been removed, the ring was machined on the outside diameter and on one end face to a surface finish of 6 μm (250 $\mu\text{in.}$), thus permitting a more sensitive inspection.

Primary consideration was given to performing a straight-beam ultrasonic inspection from the outside surface in the radial direction. During ring rolling, included foreign materials become aligned in the circumferential direction to provide a

lamellar-type discontinuity. This type of discontinuity is most readily detected from the perpendicular direction or, in this case, either from the outside or inside surfaces of the ring. Because the original discontinuities in the billet were in the center and would remain in a similar position during forging, it was anticipated that if remnants of the center condition were still present, they would be near or adjacent to the inside or bore of the ring. Therefore, a radial ultrasonic inspection from the outside using the straight-beam technique was considered to be the best method of detection.

Inspection Procedure. A straight-beam inspection was instituted as indicated, and calibration was established using the back-surface-reflection method to determine whether adequate ultrasonic penetration was available. A 25 mm (1 in.) diam, 2.25-MHz transducer was used in conjunction with the ultrasonic unit.

The outside surface was scanned in overlapping paths to ensure complete coverage. During the inspection, areas of indications were noted at approximately midheight and adjacent to the bore area; one area approximately 7 m (24 ft) long in a circumferential direction was encountered during the inspection; several smaller spot-type areas were also noted.

Evaluation of indications on the basis of applicable American Society of Mechanical Engineers (ASME) Boiler and Pressure Vessel Codes revealed that the indications would be acceptable. However, for closer evaluation, a straight-beam inspection from the face and a circumferential angle-beam inspection, in two 180° opposing directions, were performed. Straight-beam inspection from the face did not reveal indications at a normal gain or sensitivity level; they could be detected only at an extremely high sensitivity level. Angle-beam inspections showed very small low-level (approximately 10% maximum) occasional indications in the area previously noted.

Although not required by the ASME code, an axial angle-beam inspection from the outside was performed, mainly in the area of indications. Indications were readily detectable, but were not considered serious enough to reject the forging. On the basis of results of the ultrasonic inspections, the ring was considered acceptable within the required specifications. Magnetic particle inspection revealed a few small indications in the areas tested. Because severity did not appear to be indicative of the ultrasonic results, the area was conditioned by grinding and polishing to obtain an additional inspection at a greater depth from the inside surface. Subsequent magnetic particle inspection indicated a much more severe condition, which was not acceptable.

Conclusions. Metallographic investigation showed that the indications could be classified as areas of chemical segregation and nonmetallic inclusions (predominantly sulfides). These were evidently present in the center of the billet and remained in the final ring. Therefore, the ring was considered unsatisfactory for the application. Removal of the questionable metal and repair by welding was considered, but the cost would have been excessive. Replacement of the defective ring from an acceptable billet was the most economical solution.

Example 9: Ultrasonic Inspection of a 4340 Steel Shaft Forging.

The pulse-echo technique of ultrasonic inspection was selected for locating flakes, bursts, and pipe in large 4340 steel shaft forgings such as the one shown in Fig. 24.

Fig. 24 Transducer locations for radial and longitudinal ultrasonic inspection of a large steel shaft forging for

detection of flakes, bursts, and pipe. Dimensions given in inches

Equipment Specified. The ultrasonic instrument specified was a pulsed, reflection-type unit capable of testing at 1 to 5 MHz. It was also required that the instrument provide linear presentation (within $\pm 5\%$) for at least 75% of the screen height (sweep line to top of screen). It was further specified that the electronic apparatus contain a signal attenuator (accurate over its useful range to $\pm 10\%$ of the nominal attenuation ratio), which allows measurement of signals beyond the linear range of the instrument. Transducers 25 to 28 mm (1 to $1\frac{1}{8}$ in.) in diameter or 25 mm (1 in.) square were used.

Couplants having good wetting characteristics, such as SAE No. 20 or No. 30 motor oil, glycerin, pine oil, water, or a nonionic water-soluble polymer, were specified. (The above couplants, however, may not be comparable to one another, and the same couplant must be used for calibration and recording of results.) Test blocks containing flat-bottom holes were used for calibrating equipment in accordance with the above apparatus requirements. Such test blocks were used to establish recording levels for longitudinal testing.

Surface Preparation. It was required that all surfaces be machined so that surface roughness did not exceed $6\text{ }\mu\text{m}$ ($250\text{ }\mu\text{n.}$) and that surfaces contacted by transducers should be free from all extraneous material, such as scale, dirt, and paint, before the couplant was applied.

Inspection Procedure. Ultrasonic inspection was performed after heat treatment, but prior to drilling holes, cutting keyways, or otherwise machining to a contour. The entire forging was inspected using a test frequency of 2.25 MHz. Search patterns that incorporated 15% overlap between passes were scanned at a speed of less than 150 mm/s (6 in./s). Scanning from two mutually perpendicular directions (radial and longitudinal) provided complete coverage. Referring to Fig. 24, when indications were found with the transducer oriented for radial scanning (transducer location 1), the operator moved the transducer to location 2, on the end of the forging, to determine the size and axial location of the flaw. In the forging shown in Fig. 24, pipe that was 100 mm (4 in.) long by 25 mm (1 in.) thick was found in the center of the cross section and 915 mm (36 in.) from one end of the forging.

Acceptance Standards. Forgings showing a single flaw indication greater than that from a 13 mm ($\frac{1}{2}$ in.) diam flat-bottom hole were not acceptable. Forgings containing clustered or traveling indications greater than 50% of that from a 13 mm ($\frac{1}{2}$ in.) diam flat-bottom hole were not acceptable. Forgings containing a complete loss of back reflection not attributable to size, shape, or grain size were not acceptable; loss of back reflection not accompanied by an indication from a flaw was further investigated by the use of other search units. Complete loss of back reflection was assumed when the back reflection fell to less than 5% of the reference back reflection.

Example 10: Ultrasonic Inspection of an Upset-Forged 4118 Steel Shaft.

Field failures were encountered in the upset portion of forged 4118 steel shafts (Fig. 25). The failures were traced to internal cracks in the upset flange area that were initiated from gross nonmetallics. These nonmetallics, which were originally located near the center of the cross section, were pushed outward into an almost radial plane in the upsetting of the flange. When the shaft was heat treated, these planes of inclusions developed internal cracks.

Fig. 25 Upset shaft forging, of 4118 steel, that was ultrasonically inspected by the pulse-echo longitudinal wave technique. Dimensions given in inches

The location of these cracks, their orientation, and the size of the shaft all indicated that ultrasonics would be the best method for detection. Two approaches were feasible. The first was to send a longitudinal beam in from the end of the shaft, and the second was to use a shear wave from the outside diameter of the shaft adjacent to the flange. The first technique was selected because it permitted testing of shafts already assembled.

A 22 mm ($\frac{7}{8}$ in.) diam, 2.25-MHz transducer was used with a plastic wear face and an oil couplant. The shaft had a radially drilled oil hole 9 mm ($\frac{3}{8}$ in.) in diameter (note location in Fig. 25). This radial hole was used as a landmark and standard to set the sensitivity. The signal from this hole was set to give full-screen height from a known flaw-free shaft. The end of the shaft was scanned in a zone extending from the center out 40 mm ($1\frac{1}{2}$ in.) radially. The area around the longitudinal oil hole within the upset section was the area where the flaws occurred (Fig. 25).

When the shaft was tested from the short end (measured from the upset), a portion of the test area was in the shadow of the radial oil hole. In addition, because of the distance to the radial hole, the second multiple of the radial-hole signal occurred at the same point on the screen as did the flaws. For this reason and because of variation in flaw orientation, it was desirable to test the shaft from the long end as well as from the short end. In the assembled machines, the only access was to the long end of the shaft. The same standard was used from the long end of the shaft, but an instrument having higher sensitivity was required to produce a full-screen signal from the radial hole because of the added length of beam path.

The rejection level was set at 20% of full screen and was based on the size of flaws observed when the shafts were cut up. The flange portion was first cut out of the shaft and retested with a smaller-diameter transducer to better define the extent of the flaw. The section was further cut until one edge of the flaw was exposed. When possible, this reduced section was broken open through the flaw. The fracture face provided the best view of the extent and shape of the flaws. If the inclusion flaws were larger than 20 mm ($\frac{3}{4}$ in.) in diameter, they were considered rejectable even if they had not cracked in heat treatment. An attempt was made to test the shafts in the as-forged condition, but this approach was not reliable because some inclusions developed cracks during heat treatment.

Similar but slightly larger shafts were found to have the same types of flaws. These shafts were tested with the same technique as described above and initially showed a very high rate of rejection. No flaws were found when the rejected shafts were sectioned, and when the shafts were retested, no flaws were found. After some investigation, it was realized that the flaw signals were false. When a portion of the beam struck the oily surface of the longitudinal oil hole, a mode-converted wave was reflected back to the search unit. The time of travel of the mode-converted false signal coincided with the time of travel of the true flaw signals, causing rejection of the shafts. The problem was solved by removing the oil film from the longitudinal oil hole.

Example 11: Ultrasonic Inspection of B-58 Nose Landing Gear Trunnion.

The development of this inspection focused on the nose landing gear trunnions (Fig. 26). Initiation sites for stress-corrosion cracking were found to originate on the trunnion-bore inside surfaces at the forging parting plane (Fig. 27). The trunnion is made from forged aluminum alloy 7075-T6. After examination of previous failures, it was shown that these cracks may propagate to a severe condition before the trunnion fails. A manual shear wave ultrasonic inspection was developed that concentrated on these initiation sites.

Fig. 26 Location of nose landing gear trunnion (arrows) on a B-58 aircraft. Courtesy of Tom Dusz, The University of Dayton Research Institute

Fig. 27 Location of parting line on trunnion. (a) Top view of parting line. (b) Bottom view of parting line. Courtesy of Tom Dusz, The University of Dayton Research Institute

Inspection Procedure. The equipment needed for this inspection includes a flaw detection instrument capable of a test frequency of 5 MHz; a 5-MHz search unit with a special lens contoured to 45 mm (1.75 in.) cylindrical radius; a reference standard containing artificial notches 0.25, 0.50, and 1.25 mm (0.010, 0.020, and 0.050 in.) deep; and a clean oil

couplant. The reference standard is manufactured from the outer bore section of an actual trunnion. The sensitivity calibration is performed by applying sufficient couplant to the reference standard and by positioning the search unit over the 1.25 mm (0.050 in.) deep notch. A full-scale amplitude signal is obtained. The standard is scanned, and the signals are observed from the 0.25 and 0.50 mm (0.010 and 0.020 in.) deep notches. The instrument sweep delay is adjusted until the first reflected signals from the artificial defects reach their peak amplitude at the center of the screen. The sensitivity, pulse length, and reject controls are used to obtain a 95% amplitude signal from the 0.25 mm (0.010 in.) deep notch. The part is cleaned with an acceptable solvent to remove dirt, grease, tar, loose paint, and other debris. The forging parting plane and two planes parallel and 40 mm (1.5 in.) on either side of the forging parting plane are marked with ink that will not come off the part during the inspection. The areas of concern include the entire area between the parting line and the parallel lines, the bolt hole to the web on top, and the ground area on the bottom.

A defect signal first appears near the center of the screen and moves to the left as the search unit is scanned closer to the parting line. When the search unit is scanned from the parting line back toward the parallel line, the defect signal moves from the left of the screen (near the front surface noise) to the center of the screen. Figure 28 shows some typical amplitude signals that may appear on the screen. Any defect indications showing a 25% and greater amplitude signal are considered for further disassembly evaluation and/or replacement.

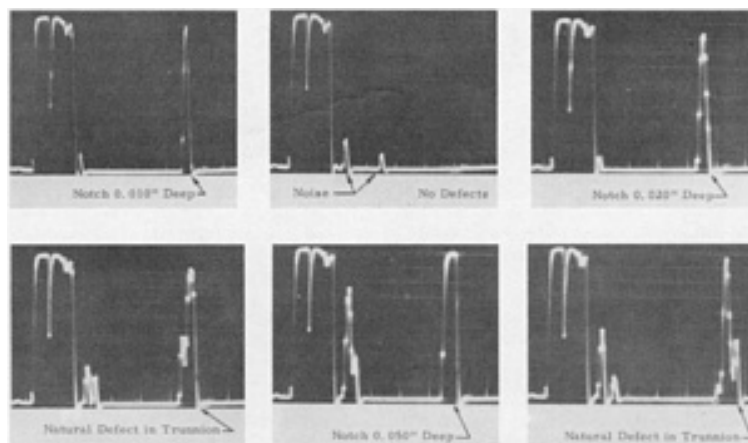

Fig. 28 Typical signals that may appear during inspection. Dimensions given in inches. Courtesy of Tom Dusz, The University of Dayton Research Institute

Conclusion. The development of this testing technique enabled inspectors to locate very gross or severe conditions before trunnion failure occurred. This greatly reduced the amount of on-aircraft failures.

Example 12: Ultrasonic Inspection by the Immersion Technique of an Aluminum Alloy Forging Having No Parallel Surfaces.

The aluminum alloy forging shown in Fig. 29(a) was ultrasonically inspected by the immersion (water) technique using a hand-held search unit. Details of the inspection conditions are given in the table accompanying Fig. 29.

(a)

(b)

Inspection technique	Immersion, hand-held unit
Mode of sound	Longitudinal wave
Frequency, MHz	5
Cable length, m (ft)	6 (20)

Water distance, mm (in.)	75 (3)
Stand-off tube, mm (in.)	25 (1) ID, 30 (1 $\frac{1}{4}$) OD

Fig. 29 Aluminum alloy forging (a) having no parallel sides that was ultrasonically inspected by the immersion technique, using the transducer assembly and stand-off tube shown in (b) and the conditions listed in the accompanying table

Reference standards were used for calibrating the oscilloscope that corresponded to full- and half-metal thickness of the thickest section of the forging and for a metal thickness of 6 mm ($\frac{1}{4}$ in.). Equivalent flat-bottom-hole sizes required for the inspection class were used in the calibration standards.

The inspection was performed to determine whether internal discontinuities of any type were present. For the, type of forging shown in Fig. 29(a), because of the continuously changing metal thicknesses and surface contours, immersion testing using a hand-held search unit was the most suitable method of ultrasonic inspection. This inspection procedure is called scrubbing. The search unit consisted of a transducer fitted with a hollow plastic tube, called a stand-off tube, to maintain a constant water distance of 75 mm (3 in.) from the entry surface (see transducer assembly, Fig. 29b). The cable and scrubber housing were attached to the scrubber cap. This portion of the unit was wrapped with watertight rubber tape because the unit is partially or totally submerged during use. The stand-off tube, while submerged, was completely filled with water, with no air gaps or bubbles present.

During inspection of the forging, the operator had to be aware of the metal thickness under examination at any particular moment. As a result of nonparallel surfaces, the screen presentation usually did not have a directly reflected first back reflection, because the back surface was not normal to the ultrasound beam path. There was a series of lesser-amplitude back reflections resulting from the sound wave bouncing around within the forging and ultimately being picked up by the search unit. These back reflections moved back and forth for short distances along the trace line. The operator had a good knowledge of the changing metal thicknesses and was able to determine the presence of a discontinuity relative to where an indication appeared on the trace line. Substantiation of a discontinuity was accomplished by inspecting the area from the opposite surface and establishing its depth relative to total metal thickness.

Nondestructive Inspection of Forgings

Eddy Current and Electromagnetic Inspection

In the nondestructive inspection of forgings, the eddy current method is commonly used to detect flaws, while the electromagnetic method is used to detect differences in microstructure, chemical composition, or hardness. Electromagnetic inspection, which is restricted to ferromagnetic materials, is sometimes categorized as a modification of the eddy current method because both techniques are based on electromagnetic principles.

In concept, eddy current equipment functions by the introduction of relatively high-frequency alternating currents into the surface areas of conductive materials. The response of the material to the induced field is then measured by a mechanism sensitive to the induced field. Detailed information is available in the article "Eddy Current Inspection" in this Volume.

Detection of Flaws

The detection of flaws in forgings by eddy current inspection is almost always done with a system consisting of a single probe that is connected to an instrument generically known as a defectometer. This system is balanced with the probe in air and is further balanced to a null value on sound material of the same composition, heat treatment, and surface condition as the forging to be inspected. Areas of the surface of the forging where flaws are suspected are scanned with the probe, which searches for an unbalance due to the flaw. Generally, the scanning is done in two directions approximately at right angles to each other.

The advantages of eddy current inspection for flaw detection include the following:

- The unbalance level can be adjusted and calibrated with notches of known depth in the same material in the same condition, which can give a reasonable estimate of the depth of the flaw. This estimate can be helpful in reaching a decision as to the serviceability of the forging
- In the event that flaws are oriented in one direction only, as with seams or rolling laps in the original stock, the technique can be automated
- Threshold gates, which are automatic signal-monitoring networks, are available to automatically signal flaws of a sufficient magnitude to be judged defective. These signals can in turn be used to mark or otherwise identify flawed forgings or locations on the forging having flaws
- The automated tester can be operated by unskilled personnel once the system has been calibrated. Solid-state electronics and their adaptation to eddy current equipment permit very stable instrumentation with no need for constant adjustment

The disadvantages of eddy current inspection for detection of flaws include the following:

- The correlation between unbalance signal and flaw depth is often not linear, for a variety of reasons. Accordingly, this method is frequently used as a go/no-go device at a depth of flaw, plus or minus a band of uncertainty. The band of uncertainty must be determined by experimental methods
- In ferrous materials, variations in the decarburization levels can render the method invalid
- This method is not suited to the detection of deep subsurface flaws

Detection of Differences in Microstructure

Differences in microstructure, which usually register as differences in hardness, can be detected by electromagnetic inspection using either encircling coils or spot probes as pickups. Regardless of whether a probe or a coil is used, the instrumentation must be set up and balanced in accordance with the manufacturer's directions. This is done without forgings in or near the pickup, with forgings in the pickup, or sometimes both with and without forgings.

Once the test setup has been established, it is necessary to have good-quality forgings of known electromagnetic response available to ensure that the instrumentation has not varied. These forgings (which are sometimes referred to as masters) must be available to personnel who are trained in the setup and maintenance of the equipment.

The advantages of electromagnetic inspection for detecting differences in microstructure include the following:

- The equipment can be electronically gated based on the response of the instrumentation to the properties of the forging
- Electromagnetic inspection can be readily automated for properties throughout a forging (usually an encircling coil) or for properties at a specific location (using a spot probe)
- Once it has been properly set up, the operation can be effectively run by unskilled personnel

The disadvantages of electromagnetic inspection for detecting differences in microstructure include the following:

- A given response can indicate more than one condition in the forging; for this reason, testing technique must be developed very carefully. For example, as illustrated in Fig. 30 by an electromagnetic S-curve for a medium-carbon steel forging, when two variables (hardness and microstructure) exist, the curve shows essentially the same height in power loss for 37 HRC as for 56.5 HRC (dashed line B-A, in Fig. 30) even though the microstructure is widely different
- Development of techniques can be done only by trained personnel; even then, a great deal of experimentation is usually required to develop procedures that will yield accurate results

Fig. 30 Relation of an electromagnetic S-curve to variations in hardness and microstructure of a medium-carbon steel forging

Nondestructive Inspection of Forgings

Radiographic Inspection

Radiography (γ -ray or x-ray) is not extensively used for the inspection of forgings for two reasons. First, the types of discontinuities most commonly located by radiography (gas porosity, shrinkage porosity, and shrinkage cavities) are not usually found in forgings. Second, for the types of internal discontinuities that are commonly found in forgings (inclusions, pipe, bursts, or flakes), ultrasonic inspection is more effective, more adaptable, and more economical.

Radiographic techniques can sometimes be helpful in the further investigation of known internal discontinuities in forgings when the presence of these discontinuities has been determined earlier by ultrasonic inspection. In sections that are not too thick to penetrate with available radiographic equipment, the size, orientation, and possibly the type of discontinuities can be evaluated by radiography.

Nondestructive Inspection of Castings

By the ASM Committee on Nondestructive Inspection of Castings*

Introduction

INSPECTION PROCEDURES for castings are established at the foundry to ensure conformance with customer drawings and documents, which are frequently based on various government, technical society, or commercial specifications. For a foundry to ensure casting quality, inspection procedures must be efficiently directed toward the prevention of imperfections, the detection of unsatisfactory trends, and the conservation of material--all of which ultimately lead to reduction in costs. Inspectors should be able to assess on sight the probable strong and weak points of a casting and know where weaknesses and faults would most likely be found.

The inspection of castings normally involves checking for shape and dimensions, coupled with aided and unaided visual inspection for external discontinuities and surface quality. Chemical analyses and tests for mechanical properties are supplemented by various forms of nondestructive inspection, including leak testing and proof loading, all of which are used to evaluate the soundness of the casting. These inspections add to the cost of the product; therefore, the initial consideration must be to determine the amount of inspection needed to maintain adequate control over quality. In some cases, this may require full inspection of each individual casting, but in other cases sampling procedures may be sufficient.

Inspection Categories

Methods for Determining Surface Quality. Cracks and other imperfections at the surface of a casting can be detected by a number of inspection techniques, including visual inspection, chemical etching, liquid penetrant inspection, eddy current inspection, and magnetic particle inspection (which can also reveal discontinuities situated immediately below the surface). All these inspection methods require clean and relatively smooth surfaces for effective results.

Methods for Detecting Internal Discontinuities. The principal nondestructive methods used for detecting internal discontinuities in castings are radiography, ultrasonic inspection, and eddy current inspection. Of these methods, radiography is the most highly developed technique for detailed inspection; it can provide a pictorial representation of the form and extent of many types of internal discontinuities. Ultrasonic inspection, which is less universally applicable, can give qualitative indications of many discontinuities. It is especially useful in the inspection of castings of fairly simple design, for which the signal pattern can be most reliably interpreted. Ultrasonic inspection can also be used to determine the shape of graphite particles in cast iron. Eddy current and other closely related electromagnetic methods are used to sort castings for variations in composition, surface hardness, and structure.

Infrared thermography (thermal inspection) has also occasionally been proposed as a method for detecting subsurface defects. However, its successful uses have generally been restricted to the detection of larger defects because of the relatively slow rates at which heat can be put into a component and because of the relatively low sensitivity of infrared detectors. Increased use of thermal inspection may occur with the introduction of pulsed video thermography, in which a very short burst of intense heat is directed at the component. The presence of near-surface defects influences the rate at which heat is dissipated from the surface, and temperature variations are detected with a high-resolution infrared camera recorded onto videotape and presented as an image on a TV monitor. The method was developed for the detection of small defects in composites and in aerospace turbine engine blades, but some initial results obtained with cast iron test plates have proved promising (Ref 1).

Methods for Dimensional Inspection. A number of techniques are used to determine the dimensional accuracy of castings. These include manual checks with micrometers, manual and automatic gages, coordinate measuring machines,

and three-dimensional automatic inspection stations (machine vision systems). This article will discuss the use of coordinate-measuring machines. Additional information on methods for dimensional inspection can be found in the Section "Inspection Equipment and Techniques" in this Volume.

Nondestructive Inspection of Castings

By the ASM Committee on Nondestructive Inspection of Castings*

Casting Defects

Foundrymen refer to the deviations in less-than-perfect castings as discontinuities, but these imperfections are more commonly termed casting defects. Some casting defects may have no influence on the function or the service life of cast components, but will give an unsatisfactory appearance or will make further processing, such as machining, more costly. Many such defects can be easily corrected by shotblast cleaning or grinding. Other defects that may be more difficult to remove can be acceptable in some locations. The casting designer must understand the differences and must write specifications that meet the true design needs.

Classification of Casting Defects. Foundrymen have traditionally used rather unique names, such as rattle, scab, buckle, snotter, and shut, to describe various casting imperfections (such terms are defined in the "Glossary of Terms" in *Casting*, Volume 15 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*). Unfortunately, foundrymen may use different nomenclature to describe the same defect. The International Committee of Foundry Technical Associations has standardized the nomenclature, starting with the identification of seven basic categories of casting defects:

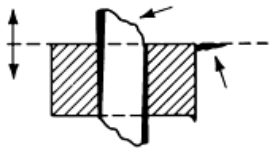

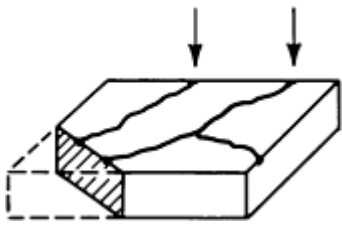

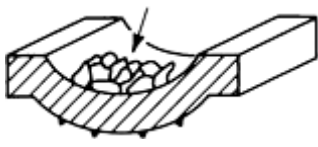

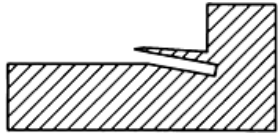

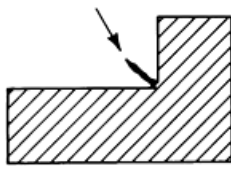

- Metallic projections
- Cavities
- Discontinuities
- Defects
- Incomplete casting
- Incorrect dimension
- Inclusions or structural anomalies

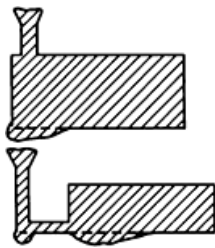

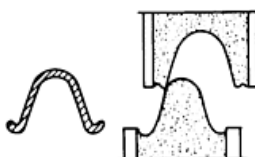

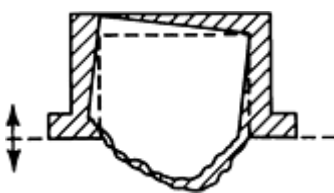

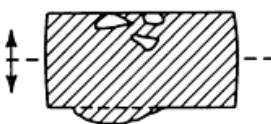

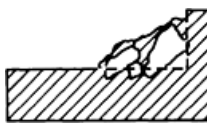

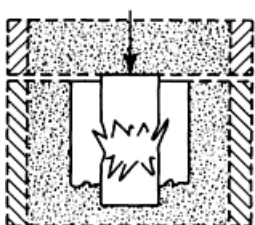

In this scheme, the term discontinuity has the specific meaning of a planar separation of the metal, that is, a crack.

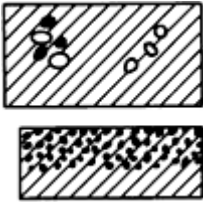

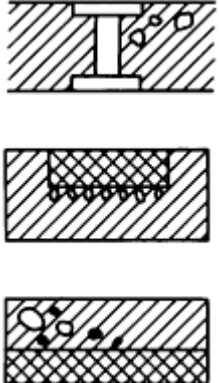

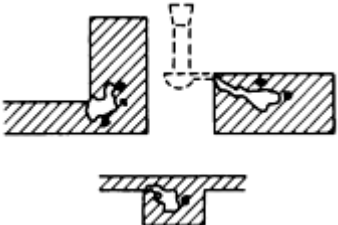

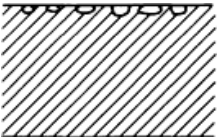

Table 1 presents some of the common defects in each category. In general, defects that can serve as stress raisers or crack promoters are the most serious. These include preexisting cracks, internal voids, and nonmetallic inclusions.

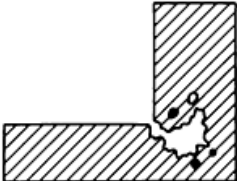

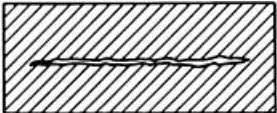

Table 1 International classification of common casting defects

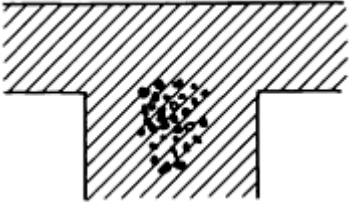

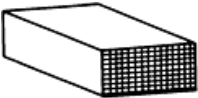

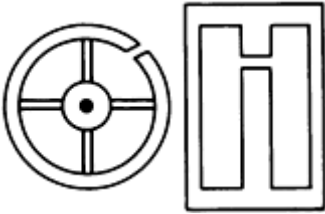

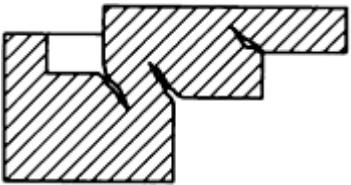

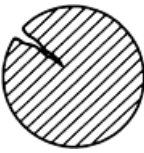

No.	Description	Common name	Sketch
Metallic Projections			
A 100:	Metallic projections in the form of fins or flash		

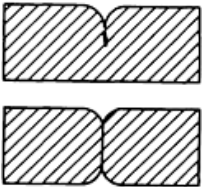

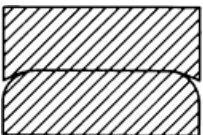

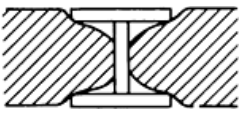

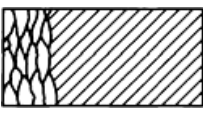

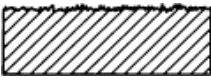

A 110:	Metallic projections in the form of fins (or flash) without change in principal casting dimensions		
A 111	Thin fins (or flash) at the parting line or at core prints	Joint flash or fins	
A 112	Projections in the form of veins on the casting surface	Veining or finning	
A 113	Network of projections on the surface of die castings	Heat-checked die	
A 114 ^(a)	Thin projection parallel to a casting surface, in re-entrant angles	Fillet scab	
A 115	Thin metallic projection located at a re-entrant angle and dividing the angle in two parts	Fillet vein	
A 120:	Metallic projections in the form of fins with changes in principal casting dimensions		
A 123 ^(a)	Formation of fins in planes related to direction of mold assembly (precision casting with waste pattern); principal casting dimensions change	Cracked or broken mold	
A 200:	Massive projections		
A 210:	Swells		

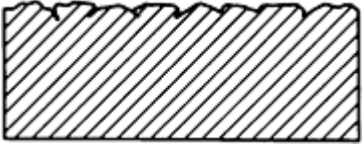

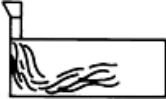

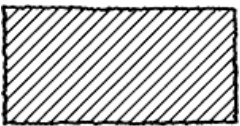

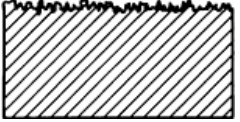

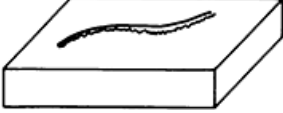

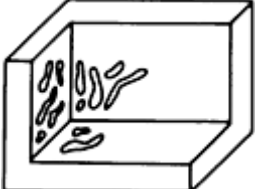

A 212 ^(a)	Excess metal in the vicinity of the gate or beneath the sprue	Erosion, cut, or wash	
A 213 ^(a)	Metal projections in the form of elongated areas in the direction of mold assembly	Crush	
A 220: Projections with rough surfaces			
A 221 ^(a)	Projections with rough surfaces on the cope surface of the casting	Mold drop or sticker	
A 222 ^(a)	Projections with rough surfaces on the drag surface of the casting (massive projections)	Raised core or mold element cutoff	
A 223 ^(a)	Projections with rough surfaces on the drag surface of the casting (in dispersed areas)	Raised sand	
A 224 ^(a)	Projections with rough surfaces on other parts of the casting	Mold drop	
A 225 ^(a)	Projections with rough surfaces over extensive areas of the casting	Corner scab	
A 226 ^(a)	Projections with rough surfaces in an area formed by a core	Broken or crushed core	
Cavities			

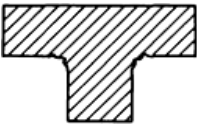

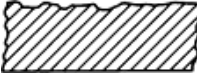

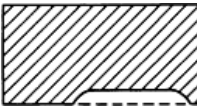

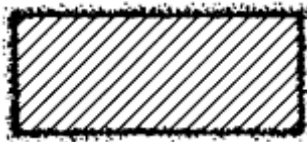

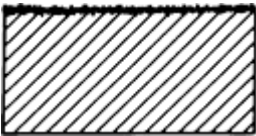

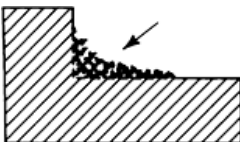

B 100:	Cavities with generally rounded, smooth walls perceptible to the naked eye (blowholes, pinholes)		
B 110:	Class B 100 cavities internal to the casting, not extending to the surface, discernible only by special methods, machining, or fracture of the casting		
B 111 ^(a)	Internal, rounded cavities, usually smooth-walled, of varied size, isolated or grouped irregularly in all areas of the casting	Blowholes, pinholes	
B 112 ^(a)	As above, but limited to the vicinity of metallic pieces placed in the mold (chills, inserts, chaplets, etc.)	Blowholes, adjacent to inserts, chills, chaplets, etc.	
B 113 ^(a)	Like B 111, but accompanied by slag inclusions (G 122)	Slag blowholes	
B 120:	Class B 100 cavities located at or near the casting surface, largely exposed or at least connected with the exterior		
B 121 ^(a)	Exposed cavities of various sizes, isolated or grouped, usually at or near the surface, with shiny walls	Surface or subsurface blowholes	
B 122 ^(a)	Exposed cavities, in re-entrant angles of the casting, often extending deeply within	Corner blowholes, draws	
B 123	Fine porosity (cavities) at the casting surface, appearing over more or less extended areas	Surface pinholes	

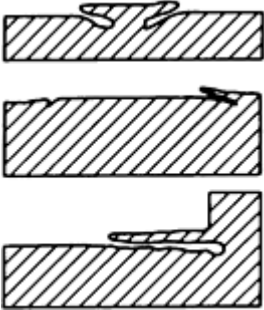

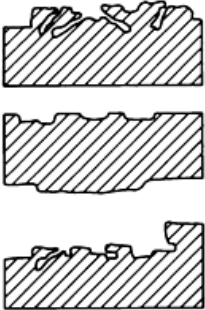

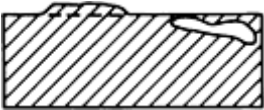

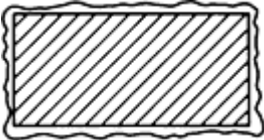

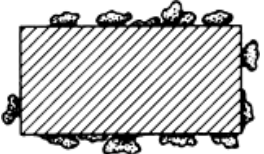

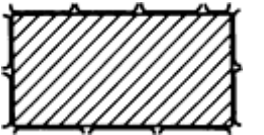

B 124 ^(a)	Small, narrow cavities in the form of cracks, appearing on the faces or along edges, generally only after machining	Dispersed shrinkage	
B 200:	Cavities with generally rough walls, shrinkage		
B 210:	Open cavity of Class B 200, sometimes penetrating deeply into the casting		
B 211 ^(a)	Open, funnel-shaped cavity; wall usually covered with dendrites	Open or external shrinkage	
B 212 ^(a)	Open, sharp-edged cavity in fillets of thick castings or at gate locations	Corner or fillet shrinkage	
B 213(a)	Open cavity extending from a core	Core shrinkage	
B 220:	Class B 200 cavity located completely internal to the casting		
B 221 ^(a)	Internal, irregularly shaped cavity; wall often dendritic	Internal or blind shrinkage	
B 222 ^(a)	Internal cavity or porous area along central axis	Centerline or axial shrinkage	
B 300:	Porous structures caused by numerous small cavities		
B 310:	Cavities according to B 300, scarcely perceptible to the naked eye		

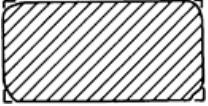

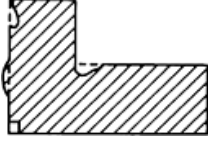

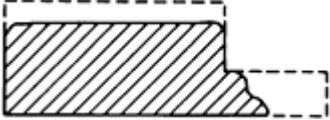

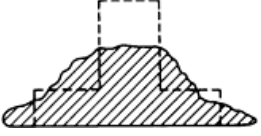

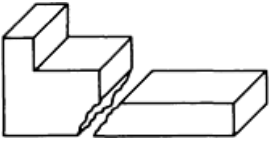

B 311 ^(a)	Dispersed, spongy dendritic shrinkage within walls of casting; barely perceptible to the naked eye	Macro- or micro-shrinkage, porosity, leakers	
Discontinuities			
C 100:	Discontinuities, generally at intersections, caused by mechanical effects (rupture)		
C 110:	Normal cracking		
C 111 ^(a)	Normal fracture appearance, sometimes with adjacent indentation marks	Breakage (cold)	
C 120:	Cracking with oxidation		
C 121 ^(a)	Fracture surface oxidized completely around edges	Hot cracking	
C 200:	Discontinuities caused by internal tension and restraints to contraction (cracks and tears)		
C 210:	Cold cracking or tearing		
C 211 ^(a)	Discontinuities with squared edges in areas susceptible to tensile stresses during cooling; surface not oxidized	Cold tearing	
C 220:	Hot cracking and tearing		
C 221 ^(a)	Irregularly shaped discontinuities in areas susceptible to tension; oxidized fracture surface showing dendritic pattern	Hot tearing	
C 222 ^(a)	Rupture after complete solidification, either during cooling or heat treatment	Quench cracking	

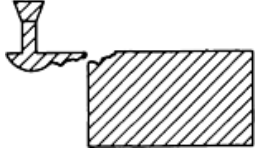

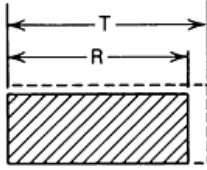

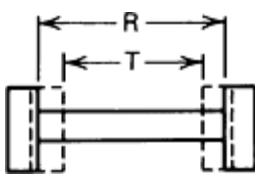

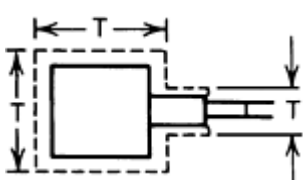

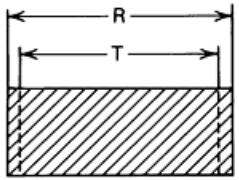

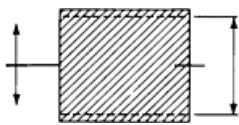

C 300:	Discontinuities caused by lack of fusion (cold shuts); edges generally rounded, indicating poor contact between various metal streams during filling of the mold		
C 310:	Lack of complete fusion in the last portion of the casting to fill		
C 311 ^(a)	Complete or partial separation of casting wall, often in a vertical plane	Cold shut or cold lap	
C 320:	Lack of fusion between two parts of casting		
C 321 ^(a)	Separation of the casting in a horizontal plane	Interrupted pour	
C 330:	Lack of fusion around chaplets, internal chills, and inserts		
C 331 ^(a)	Local discontinuity in vicinity of metallic insert	Chaplet or insert cold shut, unfused chaplet	
C 400:	Discontinuities caused by metallurgical defects		
C 410:	Separation along grain boundaries		
C 411 ^(a)	Separation along grain boundaries of primary crystallization	Conchoidal or "rock candy" fracture	
C 412 ^(a)	Network of cracks over entire cross section	Intergranular corrosion	
Defective Surface			
D 100:	Casting surface irregularities		
D 110:	Fold markings on the skin of the casting		
D 111	Fold markings over rather large areas of the casting	Surface folds, gas runs	

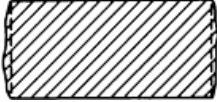

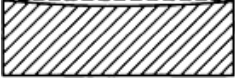

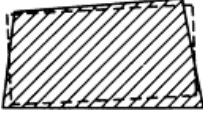

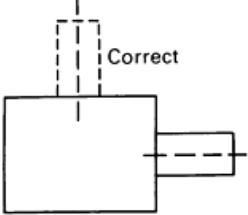

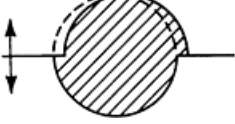

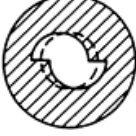

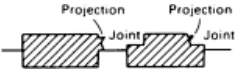

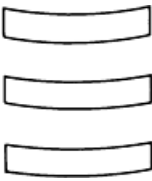

D 112	Surface shows a network of jagged folds or wrinkles (ductile iron)	Cope defect, elephant skin, laps	
D 113	Wavy fold markings without discontinuities; edges of folds at same level, casting surface is smooth	Seams or scars	
D 114	Casting surface markings showing direction of liquid metal flow (light alloys)	Flow marks	
D 120:	Surface roughness		
D 121	Depth of surface roughness is approximately that of the dimensions of the sand grains	Rough casting surface	
D 122	Depth of surface roughness is greater than that of the sand grain dimensions	Severe roughness, high pressure molding defect	
D 130:	Grooves on the casting surface		
D 131	Grooves of various lengths, often branched, with smooth bottoms and edges	Buckle	
D 132	Grooves up to 5.1 mm (0.2 in.) in depth, one edge forming a fold which more or less completely covers the groove	Rat tail	
D 133	Irregularly distributed depressions of various dimensions extending over the casting surface, usually along the path of metal flow (cast steel)	Flow marks, crow's feet	
D 134	Casting surface entirely pitted or pock-marked	Orange peel, metal mold reaction, alligator skin	

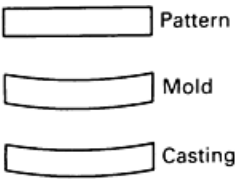

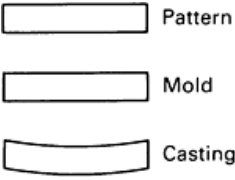

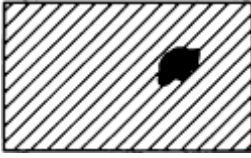

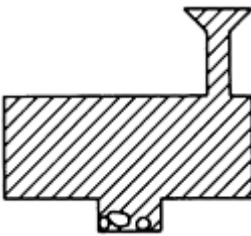

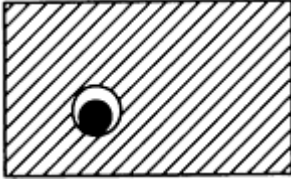

D 135	Grooves and roughness in the vicinity of re-entrant angles on die castings	Soldering, die erosion	
D 140:	Depressions in the casting surface		
D 141	Casting surface depressions in the vicinity of a hot spot	Sink marks, draw or suck-in	
D 142	Small, superficial cavities in the form of droplets or shallow spots, generally gray-green in color	Slag inclusions	
D 200:	Serious surface defects		
D 210:	Deep indentation of the casting surface		
D 211	Deep indentation, often over large area of drag half of casting	Push-up, clamp-off	
D 220:	Adherence of sand, more or less vitrified		
D 221	Sand layer strongly adhering to the casting surface	Burn on	
D 222	Very adherent layer of partially fused sand	Burn in	
D 223	Conglomeration of strongly adhering sand and metal at the hottest points of the casting (re-entrant angles and cores)	Metal penetration	
D 224	Fragment of mold material embedded in casting surface	Dip coat spall, scab	
D 230:	Plate-like metallic projections with rough surfaces, usually parallel to casting surface		

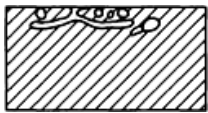

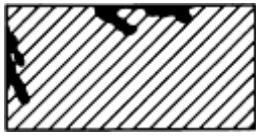

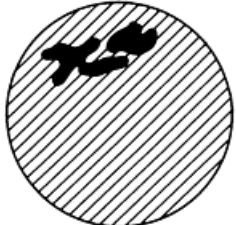

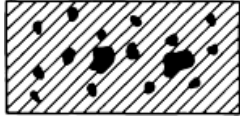

D 231 ^(a)	Plate-like metallic projections with rough surfaces parallel to casting surface; removable by burr or chisel	Scabs, expansion scabs	
D 232 ^(a)	As above, but impossible to eliminate except by machining or grinding	Cope spall, boil scab, erosion scab	
D 233 ^(a)	Flat, metallic projections on the casting where mold or core washes or dressings are used	Blackening scab, wash scab	
D 240:	Oxides adhering after heat treatment (annealing, tempering, malleablizing) by decarburization		
D 241	Adherence of oxide after annealing	Oxide scale	
D 242	Adherence of ore after malleablizing (white heart malleable)	Adherent material packing	
D 243	Scaling after anneal	Scaling	
Incomplete Casting			
E 100:	Missing portion of casting (no fracture)		
E 110:	Superficial variations from pattern shape		

E 111	Casting is essentially complete except for more or less rounded edges and corners	Misrun	
E 112	Deformed edges or contours due to poor mold repair or careless application of wash coatings	Defective coating (tear-dropping) or poor mold repair	
E 120:	Serious variations from pattern shape		
E 121	Casting incomplete due to premature solidification	Misrun	
E 122	Casting incomplete due to insufficient metal poured	Poured short	
E 123	Casting incomplete due to loss of metal from mold after pouring	Runout	
E 124	Significant lack of material due to excessive shot-blasting	Excessive cleaning	
E 125	Casting partially melted or seriously deformed during annealing	Fusion or melting during heat treatment	
E 200:	Missing portion of casting (with fracture)		
E 210:	Fractured casting		
E 211	Casting broken, large piece missing; fractured surface not oxidized	Fractured casting	
E 220:	Piece broken from casting		

E 221	Fracture dimensions correspond to those of gates, vents, etc.	Broken casting (at gate, riser, or vent)	
E 230:	Fractured casting with oxidized fracture		
E 231	Fracture appearance indicates exposure to oxidation while hot	Early shakeout	
Incorrect Dimensions or Shape			
F 100:	Incorrect dimensions; correct shape		
F 110:	All casting dimensions incorrect		
F 111	All casting dimensions incorrect in the same proportions	Improper shrinkage allowance	
F 120:	Certain casting dimensions incorrect		
F 121	Distance too great between extended projections	Hindered contraction	
F 122	Certain dimensions inexact	Irregular contraction	
F 123	Dimensions too great in the direction of rapping of pattern	Excess rapping of pattern	
F 124	Dimensions too great in direction perpendicular to parting line	Mold expansion during baking	

F 125	Excessive metal thickness at irregular locations on casting exterior	Soft or insufficient ramming, mold-wall movement	
F 126	Thin casting walls over general area, especially on horizontal surfaces	Distorted casting	
F 200:	Casting shape incorrect overall or in certain locations		
F 210:	Pattern incorrect		
F 211	Casting does not conform to the drawing shape in some or many respects; same is true of pattern	Pattern error	
F 212	Casting shape is different from drawing in a particular area; pattern is correct	Pattern mounting error	
F 220:	Shift or Mismatch		
F 221	Casting appears to have been subjected to a shearing action in the plane of the parting line	Shift	
F 222	Variation in shape of an internal casting cavity along the parting line of the core	Shifted core	
F 223	Irregular projections on vertical surfaces, generally on one side only in the vicinity of the parting line	Ramoff, ramaway	
F 230:	Deformations from correct shape		
F 231	Deformation with respect to drawing proportional for casting, mold, and pattern	Deformed pattern	 <div> <p>Pattern</p> <p>Mold</p> <p>Casting</p> </div>

F 232	Deformation with respect to drawing proportional for casting and mold; pattern conforms to drawing	Deformed mold, mold creep, springback	
F 233	Casting deformed with respect to drawing; pattern and mold conform to drawing	Casting distortion	
F 234	Casting deformed with respect to drawing after storage, annealing, machining	Warped casting	
Inclusions or Structural Anomalies			
G 100:	Inclusions		
G 110:	Metallic inclusions		
G 111 ^(a)	Metallic inclusions whose appearance, chemical analysis or structural examination show to be caused by an element foreign to the alloy	Metallic inclusions	
G 112 ^(a)	Metallic inclusions of the same chemical composition as the base metal; generally spherical and often coated with oxide	Cold shot	
G 113	Spherical metallic inclusions inside blowholes or other cavities or in surface depressions (see A 311). Composition approximates that of the alloy cast but nearer to that of a eutectic	Internal sweating, phosphide sweat	
G 120:	Nonmetallic inclusions; slag, dross, flux		
G 121 ^(a)	Nonmetallic inclusions whose appearance or analysis shows they arise from melting slags, products of metal treatment or fluxes	Slag, dross or flux inclusions, cerioxides	

G 122 ^(a)	Nonmetallic inclusions generally impregnated with gas and accompanied by blowholes (B 113)	Slag blowhole defect	
G 130: Nonmetallic inclusions; mold or core materials			
G 131 ^(a)	Sand inclusions, generally very close to the surface of the casting	Sand inclusions	
G 132 ^(a)	Inclusions of mold blacking or dressing, generally very close to the casting surface	Blacking or refractory coating inclusions	
G 140: Nonmetallic inclusions; oxides and reaction products			
G 141	Clearly defined, irregular black spots on the fractured surface of ductile cast iron	Black spots	
G 142 ^(a)	Inclusions in the form of oxide skins, most often causing a localized seam	Oxide inclusion or skins, seams	
G 143 ^(a)	Folded films of graphitic luster in the wall of the casting	Lustrous carbon films, or kish tracks	
G 144	Hard inclusions in permanent molded and die cast aluminum alloys	Hard spots	

(a) Defects that under some circumstances could contribute, either directly or indirectly, to casting failures. Adapted from *International Atlas of Casting Defects*, American Foundrymen's Society, Des Plaines, IL

Nondestructive Inspection of Castings

By the ASM Committee on Nondestructive Inspection of Castings*

Common Inspection Procedures

The inspection of castings is most often limited to visual and dimensional inspections, weight testing, and hardness testing. However, for castings that are to be used in critical applications, such as automotive or aerospace components, additional methods of nondestructive inspection are used to determine and to control casting quality.

Visual inspection of each casting ensures that none of its features has been omitted or malformed by molding errors, short running, or mistakes in cleaning. Most surface defects and roughness can be observed at this stage.

Initial sample castings from new pattern equipment should be carefully inspected for obvious defects. Liquid penetrant inspection can be used to detect surface defects. Such casting imperfections as shrinks, cracks, blows, or dross usually indicate the need for adjustment in the gating or foundry techniques. If the casting appears to be satisfactory upon visual inspection, internal quality can be checked by radiographic and ultrasonic inspection.

The first visual inspection operation on the production casting is usually performed immediately after shakeout or knockout of the casting, ensuring that major visible imperfections are detected as quickly as possible. This information, promptly relayed to the foundry, permits early corrective action to be taken with a minimum of scrap loss. The size and complexity of some sand castings require that the gates and risers be removed to permit proper inspection of the casting. Many castings that contain numerous internal cores or have close dimensional tolerances require a rapid, but fairly accurate check of critical wall dimensions. In some cases, an indicating-type caliper gage is suitable for this work, and special types are available for casting shapes that do not lend themselves to the standard types. Ultrasonic inspection is also used to determine wall thickness in such components as cored turbine blades made by investment casting. New developments in visual inspection procedures for examining component appearance are mainly based on vision systems that use electronic cameras coupled to computer-assisted image-processing systems (Ref 1).

With the development of high-sensitivity cameras having exposure times of $\frac{1}{1000}$ s, components can be inspected on moving belts. Flexibility for examining three-dimensional components can be achieved with an array of cameras multiplexed to a common image processor or with a computer-controlled camera scanning system. Such systems have been successfully applied to the inspection of printed circuit boards in the electronics industry and engineering subassemblies in automobile manufacture. These tests usually operate on a go/no-go basis; either the assembly is complete with connections correctly made or it is not correct. This is a far easier task than evaluating casting quality.

Studies that have been carried out to assess the possibility of extending such methods to iron castings have not given encouraging results. Contrast between defective and nondefective areas is low, illumination is critical, and consistent standards of inspection are difficult to maintain because of differences in reflectivity of the casting surfaces depending on whether or not they have been recently shotblasted. Even the simple task of identifying castings to determine their type is best carried out by examining their backlighted silhouette, and this provides no advantage in examining their quality.

Dimensional Inspection. Consistency of dimensions is an inescapable requirement of premium-quality castings supplied as near-net shape components on which subsequent high-speed machining operations are to be carried out (Ref 1). Customers will not accept increased machining costs due to inconsistencies in dimensions nor will they tolerate damage to flexible machining systems or transfer times resulting from poor control and inspection in foundries. Variations in dimensions represent one of the most common complaints with regard to the machinability of iron castings.

Prevention is within the control of foundries. Differences in pattern size when using multipattern plates can be virtually eliminated by the use of computer-aided design and manufacturing methods and computer numerical control machines in patternmaking (see the article "Patterns and Patternmaking" in *Casting*, Volume 15 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*). Better process control and methoding can eliminate variations in dimensions due to changes in metal composition or feeding methods. Variations in mold rigidity, caused by inadequate compaction with green sand, or the use of cold sand or insufficient curing times with cold-setting systems, which cause casting dimensions to fall outside the preset tolerance limits, can be greatly reduced by good molding and coremaking practices (see the articles "Sand Molding" and "Coremaking" in *Casting*, Volume 15 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*). Because the dimensions and weight of iron castings are directly related to their soundness and are dependent on mold rigidity, the measurement of size or weight provides a simple test for checking casting integrity and for monitoring the consistency of the moldmaking process (see the section "Weight Testing" in this article).

Casting dimensions are usually checked with dial gages, vernier calipers, micrometers, or vertical height gages, which may be hand held or incorporated into acceptance fixtures. Wall thickness measurements can be made with small hand-

held ultrasonic thickness gages. Under ideal conditions, the accuracy of these instruments is claimed to be ± 0.01 mm (± 0.0004 in.), but this is rarely achieved in practice because the surfaces are not parallel and are not machined. Instruments are available that display variations in thickness from some preset standard and provide a digital readout and a permanent record of results for statistical analysis.

Developments lie in the use of measuring systems employing capacitance, electrical contact, or linear displacement transducers. Such systems are capable of high accuracy and the output can be linked directly to microcomputers for data recording and statistical analysis to meet the requirements of statistical process control. The use of computer-aided dimensional control and statistical process control is discussed later in this article.

Laser methods of measurement using beam displacement or time-lapse techniques are available for use in machine shops where accurate measurement is required for control of automatic machining processes. At present, they are generally not well suited for measuring castings, because of their high cost and because it is difficult to make precise measurements on components having a complex shape with curved or as-cast surfaces. As these laser methods become more widely used in other industries, lower-cost systems will become available, and these might be developed for foundry use (see the article "Laser Inspection" in this Volume).

Weight Testing. Many intricately cored castings are extremely difficult to measure accurately, particularly the internal sections. It is important to ensure that these sections are correct in thickness for three main reasons:

- There should be no additional weight that would make the finished product heavier than permissible
- Sections must not be thinner than designed so as not to decrease the strength of the casting
- If hollow cavities have been reduced in area by increasing the metal thickness of the sections, any flow of liquid or gases is reduced

A ready means of testing for these discrepancies is by accurately weighing each casting or by measuring the displacement caused by immersing the casting in a liquid-filled measuring jar or vessel. In certain cases in which extreme accuracy is demanded, a tolerance of only $\pm 1\%$ of a given weight may be allowed.

Hardness testing is often used to verify the effectiveness of the heat treatment applied to actual castings. Its general correlation with the tensile strength of many ferrous alloys allows a rough prediction of tensile strength to be made.

The Brinell hardness test is most frequently used for casting alloys. A combination of large-diameter ball (5 or 10 mm) and heavy load (500 to 3000 kgf) is preferred for the most effective representation because a deep impression minimizes the influence of the immediate surface layer and of the relatively coarse microstructure. The Brinell hardness test is unsuitable for use at high hardness levels (above ~ 600 HB), because distortion of the ball indenter can affect the shape of the indentation.

Either the Rockwell or the Vickers (136° diamond pyramid) hardness test is used for alloys of extreme hardness or for high-quality and precision castings in which the large Brinell indentation cannot be tolerated. Because of the very small indentations produced in Rockwell and Vickers tests, which use loads of 150 kg or less, results must be based on the average of a number of determinations. Portable hardness testers or ultrasonic microhardness testers can be used on large castings that cannot be placed on the platform of a bench-type machine. More detailed information on hardness testing is available in *Mechanical Testing*, Volume 8 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*.

The hardness of ferrous castings can be determined from the sonic velocity of the metal if all other test conditions remain constant. This has been demonstrated on chilled rolls in determining the average hardness of the core.

Computer-Aided Dimensional Inspection

The use of computer equipment in foundry inspection operations is finding more acceptance as the power and utility of available hardware and software increase. The computerization of operations can reduce the man-hours required for inspection tasks, can increase accuracy, and can allow the analysis of data in ways that are not possible or practical with manual operations. Perhaps the best example of this, given the currently available equipment, is the application of computer technology to the dimensional inspection of castings.

Importance of Dimensional Inspection. One of the most critical determinants of casting quality in the eyes of the casting buyer is dimensional accuracy. Parts that are within dimensional tolerances, given the absence of other casting defects, can be machined, assembled, and used for their intended functions with minimal testing and inspection costs. Major casting buyers are therefore demanding statistical evidence that dimensional tolerances are being maintained. In addition, the statistical analysis of in-house processes has been demonstrated to be effective in keeping those processes under control, thus reducing scrap and rework costs.

The application of computer equipment to the collection and analysis of dimensional inspection data can increase the amount of inspection that can be performed and decrease the time required to record and analyze the results. This furnishes control information for making adjustments to tooling on the foundry floor and statistical information for reporting to customers on the dimensional accuracy of parts. Additional information on dimensional accuracy in castings can be found in the article "Dimensional Tolerances and Allowances" in *Casting*, Volume 15 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*.

Typical Equipment. A typical installation for the dimensional inspection of castings consists of an electronic coordinate measuring machine, a microcomputer interfaced to the coordinate measuring machine controller with a data transfer cable, and a software system for the microcomputer (Fig. 1). The software system should be capable of controlling the functions and memory storage of the coordinate measuring machine as well as recalling and analyzing the data it collects. The software serves as the main control element for the dimensional inspection and statistical reporting of results. Such software can be purchased or, if the expertise is available, developed in-house for highly specialized requirements.

Fig. 1 Equipment used in a typical installation for the computer-aided dimensional inspection of castings showing a coordinate measuring machine and microcomputer

Coordinate measuring machines typically record dimensions along three axes from data points specified by the user. Depending on the sophistication of the controller, such functions as center and diameter finds for circular features and the electronic rotation of measurement planes can be performed. Complex geometric constructions, such as the intersection points of lines and planes and out-of-roundness measurements, are typically off-loaded for calculation into the microcomputer. The contact probe of the coordinate measuring machine can be manipulated manually, or in the case of direct computer controlled machines, the probe can be driven by servomotors to perform the part measurement with little operator intervention. More detailed information on these machines can be found in the article "Coordinate Measuring Machines" in this Volume.

The Measurement Process. Figure 2 illustrates the general procedure that is followed in applying semiautomatic dimensional inspection to a given part. The first step is to identify the critical part dimensions that are to be measured and tracked. Nominal dimensions and tolerances are usually taken from the customer's specifications and blueprints. Dimensions that are useful in controlling the foundry process can also be selected. A data base file, including a description and tolerance limits for each dimension to be checked, is then created using the microcomputer software system.

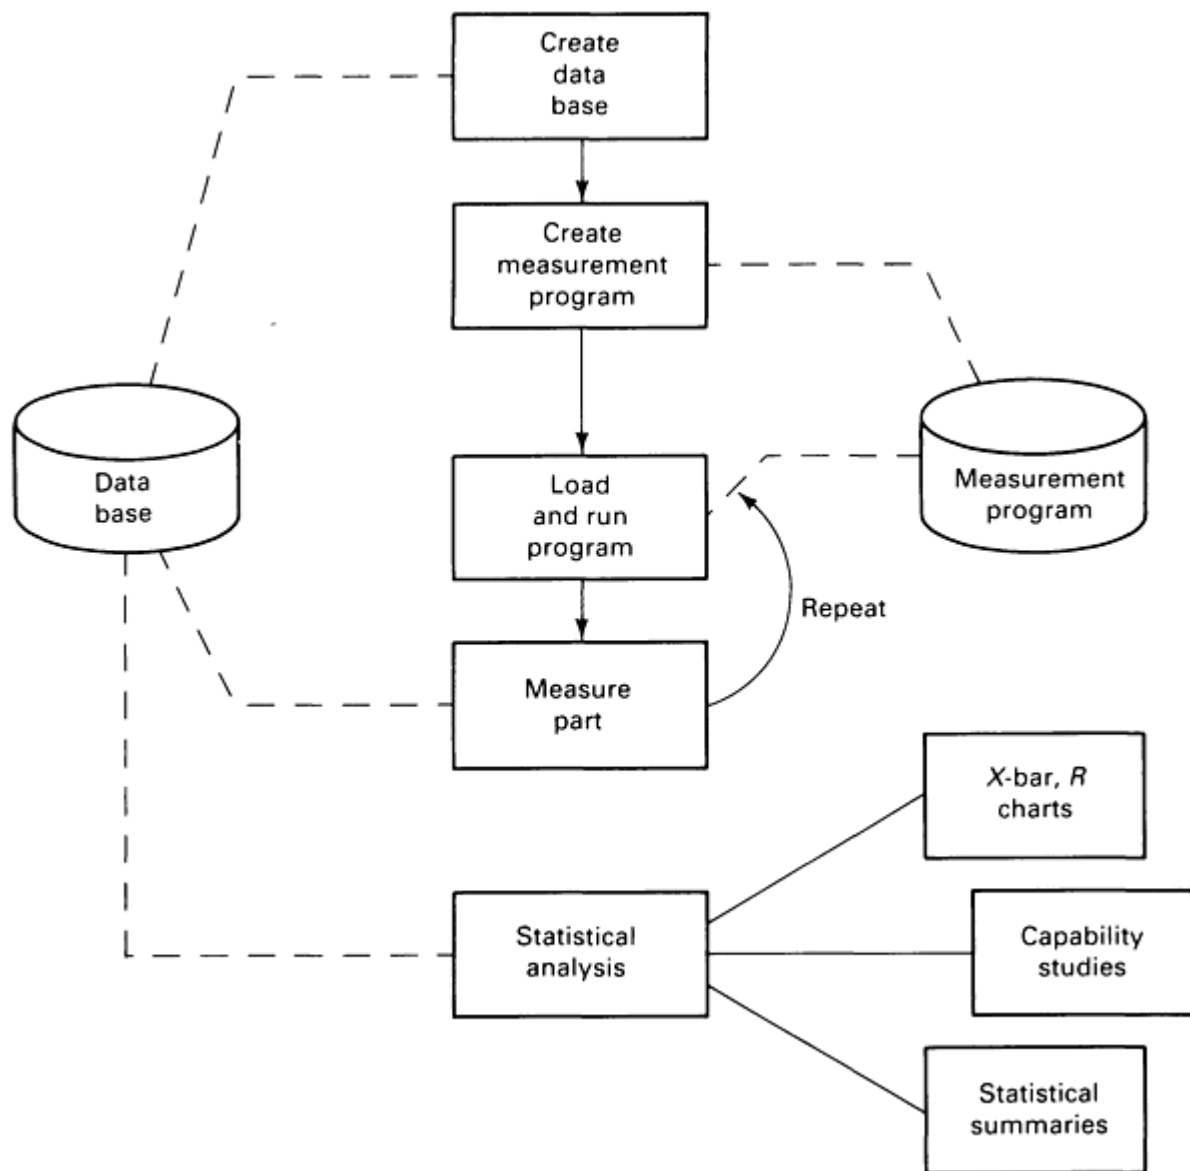

Fig. 2 Flowchart showing typical sequence of operations for computer-aided dimensional inspection

The next step in the setup process is to develop a set of instructions for measuring the part with the coordinate measuring machine. The instructions consist of commands that the coordinate measuring machine uses to establish reference planes and to measure such features as the center points of circular holes.

This measurement program can be entered in either of two ways. In the first method, the operator simply types in a list of commands that he wants the coordinate measuring machine to execute and that give the required dimensions as defined in the part data base. The second method uses a teach mode. The operator actually places a part on the worktable of the coordinate measuring machine and checks it in the proper sequence, while the computer monitors the process and stores the sequence of commands used. In either case, the result is a measurement program stored on the microcomputer that defines in precise detail how the part is to be measured. Special commands can also be included in the measurement program to display operator instructions on the computer screen while the part is being measured.

In developing the measurement program, consideration must be given to the particular requirements of the part being measured. Customer prints will normally show datum planes from which measurements are to be made. When using a cast surface to establish a datum plane, it is good practice to probe a number of points on the surface and to allow the computer to establish a best-fit plane through the points. Similarly, the center points of cast holes can best be found by probing multiple points around the circumference of the hole. Machined features can generally be measured with fewer probe contacts. When measuring complex castings, maximum use should be made of the ability of the coordinate

measuring machine to electronically rotate measurement planes without physically moving the part; unclamping and turning a part will lower the accuracy of the overall layout.

Once the setup process is complete, the dimensional inspection of parts from the foundry begins. Based on statistical considerations, a sampling procedure and frequency must be developed. Parts are then selected at random from the process according to the agreed-upon frequency. The parts are brought to the coordinate measuring machine, and the operator calls up the measurement program for that part and executes it. As the part is measured, the dimensions are sent from the coordinate measuring machine to the data base on the microcomputer. Once the measurement process is completed, information such as mold number, shift, date, and serial number should be entered by the operator so that this particular set of dimensions can be identified later. A layout report can then be generated to show how well the measured part checked out relative to the specified dimensions and tolerances. Figure 3 shows a sample report in the form of a bar graph, in which any deviation from print tolerance appears as a line of dashes to the left or right of center. A deviation outside of tolerance limits displays asterisks to flag its condition. Such a report is useful in that it gives a quick visual indication of the measurement of one casting.

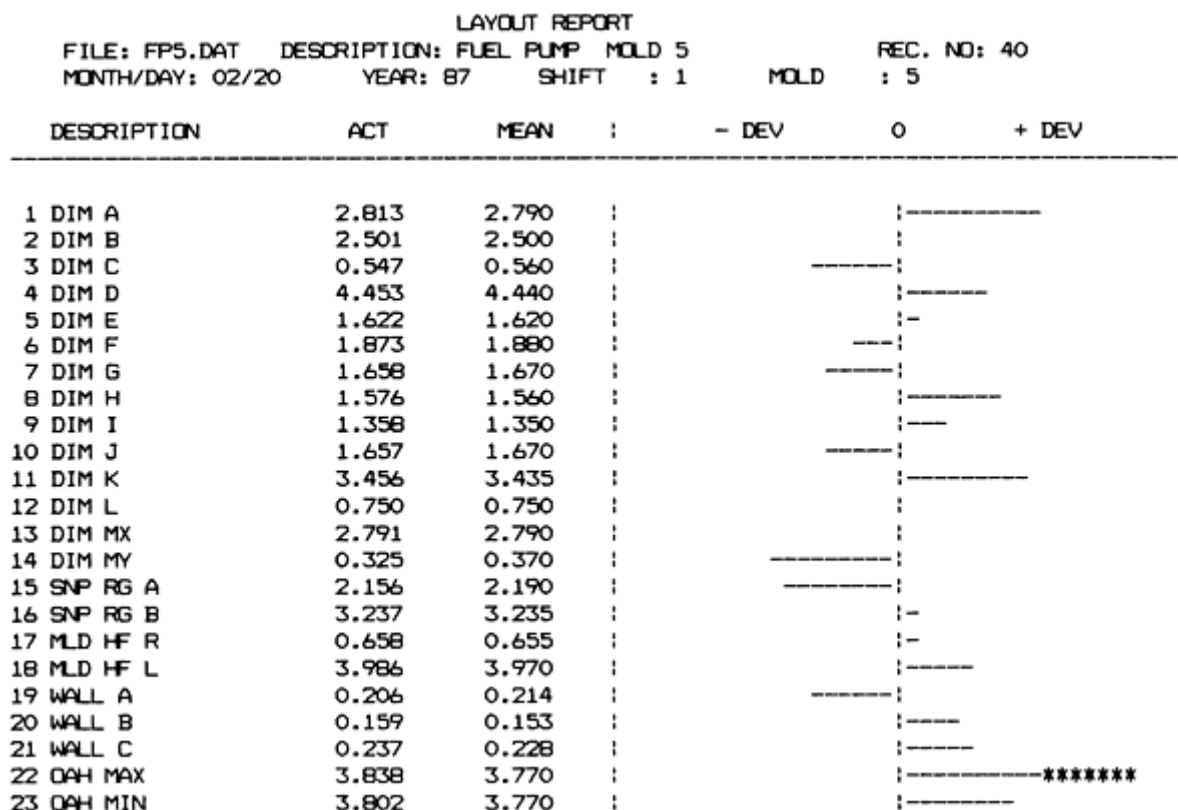

Fig. 3 Example layout report showing all dimensions measured on a single casting, with visual indication of deviations from print mean. Note out-of-tolerance condition indicated by asterisks.

Statistical analysis permits the mathematical prediction of the characteristics of all the parts produced by measuring only a sample of those parts (the principles and applications of statistics in industrial environments are discussed in the article "Statistical Quality Design and Control" in this Volume). All processes are subject to some amount of natural variation; in most processes, this variation follows a normal distribution (the familiar bell-shaped curve) when the probability of occurrence is plotted against the range of possible values. Standard deviation, a measure of the distance from center on the probability curve, is the principal means of expressing the range of measured values. For example, a spread of six standard deviations (plus or minus three standard deviations on either side of the measured mean) represents the range within which one would expect to find 99.73% of observed measurements for a normal process. This allows the natural variation inherent in the process to be quantified.

Control Charts. With statistical software incorporated into the microcomputer system, the results of numerous measurements of the same part can be analyzed to determine, first, how well the process is staying in control, that is, whether the natural variations occurring in a given measurement are within control limits and whether any identifiable

trends are occurring. This is done by using a control chart (Fig. 4), which displays the average values and ranges of groups of measurements plotted against time. Single-value charts with a moving range can also be helpful. The control limits can also be calculated and displayed. With the computer, this type of graph can be generated within seconds. Analysis of the graph may show a developing trend that can be corrected by adjusting the tooling before out-of-tolerance parts are made.

Fig. 4 Control chart with average of groups of measurements (\bar{X} values) plotted above and ranges within the groups (R) plotted below. Control limits have been calculated and placed on the chart by the computer.

Statistical Summary Report. The second type of analysis shows the capability of the process, that is, how the range of natural variation (as measured by a specified multiple of the standard deviation) compares with the tolerance range specified for a given dimension. An example of a useful report of this type is shown in Fig. 5. This information is of great interest both to the customer and the process engineer because it indicates whether or not the process being used to produce the part can hold the dimensions within the required tolerance limits. The user must be aware that different methods of capability analysis are used by different casting buyers, so the software should be flexible enough to accommodate the various methods of calculation that might be required.

68 Parts included in analysis
Actual Sigma calculated

$$\text{Process Capability} = \frac{\text{Blueprint Tolerance}}{6 \times \text{Sigma}}$$

Fig. 5 Statistical summary report showing the mean of measured observations, the blueprint specification for the mean, the difference between specified and measured means, the tolerance, the standard deviation of the measured dimensions, and the capability of the process. These calculations are performed for all measured dimensions on the part.

Histograms. An alternative method of assessing capability involves the use of a histogram, or frequency plot. This is a graph that plots the number of occurrences within successive, equally spaced ranges of a given measured dimension. Figure 6 shows an example output report of this type. A graph such as this, which has superimposed upon it the tolerance limits for the dimension being analyzed, allows a quick, qualitative evaluation of the variation and capability of the process. It also allows the normality of the process to be judged through comparison with the expected bell-shaped curve of a normal process.

Fig. 6 Frequency plot for one measured dimension showing the distribution of the measurements

Other Applications for Computer-Aided Inspection. The general sequence described for semiautomatic dimensional inspection can be applied to a number of other inspection criteria. Examples would include pressure testing or defect detection by electronic vision systems. The statistical analysis of scrap by defect types is also very helpful in identifying problem areas. In some cases, direct data input to a computer may not be feasible, but the benefits of entering data manually into a statistical analysis program should not be overlooked. The computer allows rapid analysis of large amounts of data so that statistically significant trends can be detected and proper attention paid to appropriate areas for improvement. The benefits and costs of each anticipated application of automation to a particular situation, as well as the feasibility of applying state-of-the-art equipment, need to be studied as thoroughly as possible prior to implementation.

Nondestructive Inspection of Castings

By the ASM Committee on Nondestructive Inspection of Castings*

Liquid Penetrant Inspection

Liquid penetrant inspection essentially involves a liquid wetting the surface of a workpiece, flowing over that surface to form a continuous and uniform coating, and migrating into cracks or cavities that are open to the surface. After a few minutes, the liquid coating is washed off the surface of the casting, and a developer is placed on the surface. The developer is stained by the liquid penetrant as it is drawn out of the cracks and cavities. Liquid penetrants will highlight surface defects so that detection is more certain. Details of this method can be found in the article "Liquid Penetrant Inspection" in this Volume.

Liquid penetrant inspection should not be confined to as-cast surfaces. For example, it is not unusual for castings of various alloys to exhibit cracks (frequently intergranular) on machined surfaces. A pattern of cracks of this type may be the result of intergranular cracking throughout the material because of an error in composition or heat treatment, or the cracks may be on the surface only as a result of machining or grinding. Surface cracking may result from insufficient machining allowance, which does not allow for complete removal of imperfections produced on the as-cast surface, or it may result from faulty machining techniques. If imperfections of this type are detected by visual inspection, liquid penetrant inspection will show the full extent of such imperfections, will give some indication of the depth and size of the defect below the surface by the amount of penetrant absorbed, and will indicate whether cracking is present throughout the section.

Liquid penetrant inspection is sometimes used in conjunction with another nondestructive method. Such is the case in the following example.

Example 1: Tail Rotor Gearbox Failure on the H-53 Helicopter.

The H-53 tail rotor gearbox mounting lugs experienced failures that resulted in at least two aircraft accidents. The gearbox is a magnesium casting, either AZ-91 or ZE-41. Initially, only visual inspection using a 10× magnifying glass was required. Initiation sites for the cracking were found to be localized in a few areas adjacent to the attached lugs (Fig. 7). A manual eddy current inspection was developed that concentrated on the potential initiation sites. If an indication was found, then a fluorescent penetrant inspection was performed as a backup inspection.

Fig. 7 Helicopter transmission mounting lug. Note: bolt is shown removed for clarity. Bolt is not removed for eddy current inspection.

Inspection Procedure. An eddy current tester with a flawgate and shielded probes was used to perform the inspection. The instrument is calibrated using standard magnesium alloy (either AZ-91 or ZE-41) calibration blocks. The tester is calibrated on a 0.50 mm (0.020 in.) slot to achieve a minimum 150 A deflection. The flawgate is calibrated to activate for meter deflection greater than 150 A. The part is scanned very slowly over all critical areas. As an aid for the inspection of the lug edges, a wooden toothpick is taped to the probe to maintain a constant probe-to-edge distance. A positive indication--meter deflection greater than 150 A--requires a fluorescent penetrant inspection.

In preparation for the fluorescent penetrant inspection, the paint in the area to be inspected is removed. The required penetrant material sensitivity is level II or III and is used with a halogenated solvent remover and non-aqueous developer. Clean cloths moistened with solvent cleaner are required for the cleaning step. The inspection area is never flushed with solvent. An initial inspection is required before the developer is applied. If no indications are noted, developer is applied. When an indication is noted, it is wiped with a cotton swab moistened with solvent, and the area is inspected for the indication bleed-back. A 30-min penetrant dwell time is required. The minimum required dwell time between cleaning and application of the developer is 10 min before inspection. The minimum developer dwell time is half the penetrant dwell time, and a maximum developer dwell time is not to exceed the penetrant dwell time.

After the inspection, all developer residue is removed from the mounting lug. Areas of greatest concern include the mount pad radius areas, lug flanges along edges, and the mounting pad. After completion of penetrant inspection, the finishes on

the mounting lug are replaced in such a way that the eddy current inspection is not hindered and the visual inspection is enhanced. The visual inspection is enhanced by painting the lugs light gray or white.

Conclusions. These inspections were performed during scheduled inspection intervals until magnesium alloy castings were replaced with A356.0 aluminum alloy castings.

Nondestructive Inspection of Castings

By the ASM Committee on Nondestructive Inspection of Castings*

Magnetic Particle Inspection

Magnetic particle inspection is a highly effective and sensitive technique for revealing cracks and similar defects at or just beneath the surface of castings made of ferromagnetic metals. The capability of detecting discontinuities just beneath the surface is important because such cleaning methods as shot or abrasive blasting tend to close a surface break that might go undetected in visual or liquid penetrant inspection.

When a magnetic field is generated in and around a casting made of a ferromagnetic metal and the lines of magnetic flux are intersected by a defect such as a crack, magnetic poles are induced on either side of the defect. The resulting local flux disturbance can be detected by its effect on the particles of a ferromagnetic material, which become attracted to the region of the defect as they are dusted on the casting. Maximum sensitivity of indication is obtained when a defect is oriented in a direction perpendicular to the applied magnetic field and when the strength of this field is sufficient to saturate the casting being inspected.

Equipment for magnetic particle inspection uses direct or alternating current to generate the necessary magnetic fields. The current can be applied in a variety of ways to control the direction and magnitude of the magnetic field.

In one method of magnetization, a heavy current is passed directly through the casting placed between two solid contacts. The induced magnetic field then runs in the transverse or circumferential direction, producing conditions favorable to the detection of longitudinally oriented defects. A coil encircling the casting will induce a magnetic field that runs in the longitudinal direction, producing conditions favorable to the detection of circumferentially (or transversely) oriented defects. Alternatively, a longitudinal magnetic field can be conveniently generated by passing current through a flexible cable conductor, which can be coiled around any metal section. This method is particularly adaptable to castings of irregular shape. Circumferential magnetic fields can be induced in hollow cylindrical castings by using an axially disposed central conductor threaded through the casting.

Small castings can be magnetic particle inspected directly on bench-type equipment that incorporates both coils and solid contacts. Critical regions of larger castings can be inspected by the use of yokes, coils, or contact probes carried on flexible cables connected to the source of current; this setup enables most regions of castings to be inspected. Equipment and techniques associated with this method can be found in the article "Magnetic Particle Inspection" in this Volume.

Nondestructive Inspection of Castings

By the ASM Committee on Nondestructive Inspection of Castings*

Eddy Current Inspection

Eddy current inspection consists of observing the interaction between electromagnetic fields and metals. In a basic system, currents are induced to flow in the testpiece by a coil of wire that carries an alternating current. As the part enters the coil, or as the coil in the form of a probe or yoke is placed on the testpiece, electromagnetic energy produced by the coils is partly absorbed and converted into heat by the effects of resistivity and hysteresis. Part of the remaining energy is reflected back to the test coil, its electrical characteristics having been changed in a manner determined by the properties of the testpiece. Consequently, the currents flowing through the probe coil are the source of information describing the

characteristics of the testpiece. These currents can be analyzed and compared with currents flowing through a reference specimen.

Eddy current methods of inspection are effective with both ferromagnetic and nonferromagnetic metals. Eddy current methods are not as sensitive to small, open defects as liquid penetrant or magnetic particle methods are. Because of the skin effect, eddy current inspection is generally restricted to depths less than 6 mm ($\frac{1}{4}$ in.). The results of inspecting ferromagnetic materials can be obscured by changes in the magnetic permeability of the testpiece. Changes in temperature must be avoided to prevent erroneous results if electrical conductivity or other properties, including metallurgical properties, are being determined.

Applications of eddy current and electromagnetic methods of inspection to castings can be divided into the following three categories:

- Detecting near-surface flaws such as cracks, voids, inclusions, blowholes, and pinholes (eddy current inspection)
- Sorting according to alloy, temper, electrical conductivity, hardness, and other metallurgical factors (primarily electromagnetic inspection)
- Gaging according to size, shape, plating thickness, or insulation thickness (eddy current or electromagnetic inspection)

The following example demonstrates the use of eddy current inspection for the evaluation of an induction-hardened surface on a gray iron casting.

Example 2: Eddy Current Inspection of Hardened Valve Seats on Gray Iron Automotive Cylinder Heads.

Exhaust-valve seats on gray iron automotive engine cylinder heads were induction hardened to withstand use with lead-free fuels. The seats were specified to be hardened to 50 HRC to a depth of 1.27 to 2.03 mm (0.050 to 0.080 in.). Failure to achieve these depths could lead to excessive recession of the seat, causing premature failure.

To establish the feasibility of, and the conditions for, eddy current inspection of cylinder heads having valve seats of different diameters, an adjustable probe was made using a 10 mm (0.400 in.) diam standard probe. The end was machined to a 120° conical point, and the probe was mounted in a plastic holder. A scrap valve stem mounted in the holder was used to position the probe on the valve seat. The probe was centered on the valve seat by moving the probe in its holder and by the adjusting screw. After the inspection conditions were established, rugged units for use by production inspectors were made of stainless steel with the protected probe in a fixed position to suit the cylinder-head seat.

In operation, the probe was brought into intimate contact with the hardened surface, and a meter reading was taken. Positioning of the probe on the valve seat is shown in Fig. 8. The meter reading, taken from an instrument calibrated from -100 to +100, was compared with a developed chart for case depth versus meter reading (a linear relationship). A meter reading of 0 was established for 50 HRC at a depth of 1.27 mm (0.050 in.) and -40 for 2.03 mm (0.080 in.). The instrumentation was set up to respond to A_r (resistive component). Inspection was performed at a frequency of 2 kHz. Extensive laboratory and production inspection has shown a standard deviation, σ of ± 0.8 mm (± 0.03 in.) and a confidence limit of 3σ for the total data generated.

Fig. 8 Eddy current inspection using an adjustable probe for determining case depth of an induction-hardened gray iron valve seat.

Nondestructive Inspection of Castings

By the ASM Committee on Nondestructive Inspection of Castings*

Radiographic Inspection

Radiographic inspection is a process of testing materials using penetrating radiation from an x-ray generator or a radioactive source and an imaging medium, such as x-ray film or an electronic device. In passing through the material, some of the radiation is attenuated, depending on the thickness and the radiographic density of the material, while the radiation that passes through the material forms an image. The radiographic image is generated by variations in the intensity of the emerging beam.

Internal flaws, such as gas entrapment or nonmetallic inclusions, have a direct effect on the attenuation. These flaws create variations in material thickness, resulting in localized dark or light spots on the image.

The term radiography usually implies a radiographic process that produces a permanent image on film (conventional radiography) or paper (paper radiography or xero radiography), although in a broad sense it refers to all forms of radiographic inspection. When inspection involves viewing an image on a fluorescent screen or image intensifier, the radiographic process is termed filmless or real-time inspection. When electronic nonimaging instruments are used to measure the intensity of radiation, the process is termed radiation gaging. Tomography, a radiation inspection method adapted from the medical computerized axial tomography scanner, provides a cross-sectional view of a testpiece. All of the above terms are primarily used in connection with inspection that involves penetrating electromagnetic radiation in the form of x-rays or γ -rays. Neutron radiography refers to radiographic inspection using neutrons rather than electromagnetic radiation.

The sensitivity, or the ability to detect flaws, of radiographic inspection depends on close control of the inspection technique, including the geometric relationships among the point of x-ray emission, the casting, and the x-ray imaging plane. The smallest detectable variation in metal thickness lies between 0.5 and 2.0% of the total section thickness. Narrow flaws, such as cracks, must lie in a plane approximately parallel to the emergent x-ray beam to be imaged; this requires multiple exposures for x-ray film techniques and a remote-control parts manipulator for a real-time system.

Real-time systems have eliminated the need for multiple exposures of the same casting by dynamically inspecting parts on a manipulator, with the capability of changing the x-ray energy for changes in total material thickness. These capabilities have significantly improved productivity and have reduced costs, thus enabling higher percentages of castings

to be inspected and providing instant feedback after repair procedures. Figures 9 and 10 show real-time digital radiography images of automotive components.

Fig. 10 Evaluation of cast transmission housing assembly. (a) Photograph of cast part. (b) Digital radiography image used to verify the steel spring pin and shuttle valve assembly through material thicknesses ranging from 3 mm ($\frac{1}{8}$ in.) in the channels to 25 mm (1 in.) in the rib sections of the casting. Courtesy of B.G. Isaacson, Bio-Imaging Research, Inc.

Advances. Several advances have been made to assist the industrial radiographer. These include the computerization of the radiographic standard shooting sketch, which graphically shows areas to be x-rayed and the viewing direction or angle at which the shot is to be taken, and the development of microprocessor-controlled x-ray systems capable of storing different x-ray exposure parameters for rapid retrieval and automatic warm-up of the system prior to use. The advent of digital image-processing systems and microfocus x-ray sources (near point source), producing energies capable of penetrating thick material sections, have made real-time inspection capable of producing images equal to, and in some cases superior to, x-ray film images by employing geometric relations previously unattainable with macrofocus x-ray systems. The near point source of the microfocus x-ray system virtually eliminates the edge unsharpness associated with larger focus devices.

Digital image processing can be used to enhance imagery by multiple video frame integration and averaging techniques that improve the signal-to-noise ratio of the image. This enables the radiographer to digitally adjust the contrast of the image and to perform various edge enhancements to increase the conspicuity of many linear indications (Fig. 11).

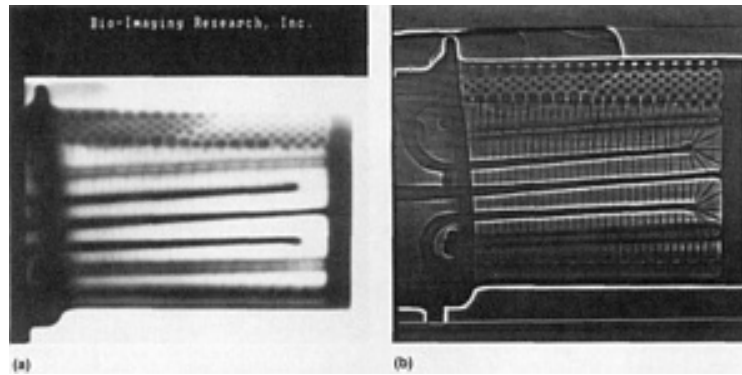

Fig. 11 Digital radiography images of an investment cast jet engine turbine blade showing detail through a wide range in material thickness. The trailing edge of the blade (along the top of the image) is 2 mm (0.080 in.) thick, the root section of the blade (to the far left in the image) is 19 mm (0.75 in.) thick, and the shelf area (to the right of the root section) is 25 mm (1 in.) thick. The image shown in (a) is unprocessed; the image in (b) is processed to subdue the background and to enhance edges and internal features. Courtesy of B.G. Isaacson, Bio-Imaging Research, Inc.

Interpretation of the radiographic image requires a skilled specialist who can establish the correct method of exposing the castings with regard to x-ray energies, geometric relationships, and casting orientation and can take all of these factors into account to achieve an acceptable, interpretable image. Interpretation of the image must be performed to establish standards in the form of written or photographic instructions. The inspector must also be capable of determining if the localized indication is a spurious indication, a film artifact, a video aberration, or a surface irregularity. The article "Radiographic Inspection" in this Volume provides additional information on real-time digital systems.

Computed tomography, also known as computerized axial tomography (or CAT scanning), is a more sophisticated x-ray imaging technique originally developed for medical diagnostic use (Ref 2). It is the complete reconstruction by computer of a tomographic plane, or slice of an object. A collimated (fan-shaped) x-ray beam is passed through a section of the part and is intercepted by a detector on the other side. The part is rotated slightly, and a new set of measurements is made; this process is repeated until the part has been rotated 180°.

The resulting image of the slice (tomogram) is formed by computer calculations based on electronic measurement (digital sampling) of the radiation transmitted through the object along different paths during the rotating scan. The data thus accumulated are used to compute the densities of each point in the cross section, enabling the computer to reconstruct a two-dimensional visual image of the slice.

The shapes of internal features are determined by their computed densities. After one slice is produced through a complete rotation, either the part or the radiation source and detector can be moved and a three dimensional image built up through the scanning of successive slices.

Compared to electronic radiography, computed tomography provides increased sensitivity and detection capabilities. The contrast resolution of a good-quality tomographic image is 0.1 to 0.2%, which is approximately two orders of magnitude better than with x-ray film.

In addition, images are produced in a quantitative, ready-to-use digital format (Ref 3). They provide detailed physical information, such as size, density, and composition, to aid in evaluating defects. Methods are being developed to use this information to predict failure modes or system performance under operating loads. The data can also be easily manipulated to obtain various types of images, to develop automated flaw detection techniques, and to promote efficient archiving. Figures 12 and 13 illustrate the uses of computed tomography for examining castings. More detailed information can be found in the article "Industrial Computed Tomography" in this Volume.

Fig. 12 Computed tomographic images of a die cast aluminum automotive piston. (a) Photograph of cast part. (b) Vertical slice through the piston shows porosity as dark spots in the crown area (point A) and counterbalance area (point B). (c) Transverse slice through the crown of the piston verifies the porosity; the smallest void that is visible is 0.4 mm (0.016 in.) in diameter. (d) Transverse slice through the counterbalance area also verifies porosity. Dimensional analysis of the piston walls is possible to an accuracy of $\pm 50 \mu\text{m}$ (± 0.002 in.). Nondestructive Inspection of Castings

By the ASM Committee on Nondestructive Inspection of Castings*

Ultrasonic Inspection

Ultrasonic inspection is a nondestructive method in which beams of high-frequency acoustic energy are introduced into the material under evaluation to detect surface and subsurface flaws and to measure the thickness of the material or the distance to a flaw (see the article "Ultrasonic Inspection" in this Volume for details). An ultrasonic beam will travel through a material until it strikes an interface or defect. Interfaces and defects interrupt the beam and reflect a portion of the incident acoustic energy. The amount of energy reflected is a function of the nature and orientation of the interface or flaw as well as the acoustic impedance of such a reflector. Energy reflected from various interfaces or defects can be used to define the presence and locations of defects, the thickness of the material, or the depth of the defect beneath a surface.

The advantages of ultrasonic tests are as follows:

- High sensitivity, which permits the detection of minute cracks
- Great penetrating power, which allows the examination of extremely thick sections
- Accuracy in measuring of flaw position and estimating defect size

Ultrasonic tests have the following limitations:

- Size-contour complexity and unfavorable discontinuity orientation can pose problems in interpreting the echo pattern
- Undesirable internal structure--for example, grain size, structure, porosity, inclusion content, or fine dispersed precipitates--can similarly hinder interpretation
- Reference standards are required

Effect of Casting Shape. Because castings are rarely simple flat shapes, they are not as easy to inspect as such products as rolled rectangular bars. The reflections of a sound beam from the back surface of a parallel-sided casting and a discontinuity are shown schematically in Fig. 14(a), together with the relative heights and positions of the reflections of the two surfaces on an oscilloscope screen. A decrease in the back reflection at the same time as the appearance of a discontinuity echo is a secondary indication of the presence of a discontinuity. However, if the back surface of the casting at a particular location for inspection is not approximately at a right angle to the incident sound beam, the beam will be reflected to remote parts of the casting and not directly returned to the detector. In this case, as shown in Fig. 14(b), there is no back reflection to monitor as a secondary indication.

Fig. 14 Schematic of the effect of casting shapes on reflection and oscilloscope screen display of sound beams. See text for discussion.

Many castings contain cored holes and changes in section, and echoes from holes and changes in section can interfere with echoes from discontinuities. As shown in Fig. 14(c), the echo from the cored hole overlaps the echo from the discontinuity on the oscilloscope screen. The same effect is shown in Fig. 14(d), in which echoes from the discontinuity and the casting fillets at a change in section are shown overlapping on the oscilloscope.

Curved surfaces do not permit adequate or easy coupling of the flat search units to the casting surface, especially with contact double search units. This can be overcome to some extent by using a suitable viscous couplant, but misleading results may be produced because multiple reflections in the wedge of fluid between the search unit and the surface can result in echoes on the screen in those positions where discontinuity echoes may be expected to appear. Because the reflections inside the couplant use energy that would otherwise pass into the casting, the back echo decreases, and this decrease might be interpreted as confirmation of the presence of a discontinuity. On cylindrical surfaces, the indication will change as a double search unit is rotated. The wedge effect is least when the division between the transmitting and receiving transducers is parallel to the axis of the cylinder. Wedge effects in the couplant are a particular problem on castings curved in two directions. One solution in this case is to use a small search unit so that the wedge is short, although the resolution and sensitivity may be reduced.

If the surface of the casting to be inspected is of regular shape, such as the bore of a cylinder in an engine block, the front of the search unit can be shaped to fit the curvature of the surface. These curved shapes form an acoustic lens that will alter the shape of the sound beam, but unless the curvature is severe, this will not prevent adequate accuracy in the

inspection. Cast-on flat metal pads for application of the ultrasonic search unit are very effective and allow particular areas of the casting to be inspected.

Subsurface Defects. Defects such as small blowholes, pinholes, or inclusions that occur within depths of 3 or 4 mm (0.1 or 0.15 in.) of a cast surface are among the most difficult to detect (Ref 1). They are beyond the limits of sensitivity of conventional magnetic particle methods and are not easily identified by eddy current techniques. They usually fall within the dead zone (the surface layer that cannot be inspected) of conventional single-crystal ultrasonic probes applied directly to a cast surface, although some improvement can be obtained by using twin crystal probes focused to depths not too far below the surface. The other alternative using contact methods of ultrasonic testing is to employ angle probes, but this complicates the procedures and interpretation methods to the point at which they can only be applied satisfactorily under the close control of skilled operators.

Freedom from such surface defects is, however, a very important aspect of the quality of castings. Apart from their effect in reducing bending fatigue properties, such defects are frequently revealed at late stages in the machining of a component, leading to its rejection.

Ultrasonic methods for detecting subsurface defects are much more successful when the dead zone beneath the as-cast surface is virtually eliminated by using immersion methods in which the probe is held away from the cast surface at a known controlled distance, with coupling being obtained through a liquid bath. To make such methods consistent and reliable, the test itself must be automated. Semiautomatic equipment has been developed for examining castings such as cylinder heads by this method (Ref 1). With this equipment, the casting is loaded into a cradle from a roller track and is then transferred using a hoist into the immersion tank until the surface of the casting to be inspected is just submerged in the liquid. Depth of immersion is closely controlled because the customer will not permit liquid to be left in the internal passageways of the cylinder head. The immersed surface of the casting is then scanned manually using an ultrasonic probe held at a fixed distance from the casting surface. This equipment is suitable for testing any casting requiring examination over a flat surface.

Internal Defects. Ultrasonic inspection is a well-established method for the detection of internal defects in castings. Test equipment developments, automated testing procedures, and improvements in determining the size and position of defects, which is essential to assessing whether or not their presence will likely affect the service performance of the casting, have contributed to the increasing use of ultrasonic test equipment.

For determining the position and size of defects, the usual method of presentation of ultrasonic data is an A-scan, in which the amplitude of the echoes from defects is shown on a time base and has well-known limitations (Ref 1). Sizing relies on measuring the drop in amplitude of the echo as the probe is passed over the boundary of a defect or measuring the reduction in the amplitude of the back wall echo due to the scattering of sound by the defect. In most cases, sizing is approximate and is restricted to one or two dimensions. Improvements in data presentation in the form of B-scans and C-scans that present a plan view through the section of the component provide a marked improvement in defining defect positions and size in two or three dimensions. Such displays have been used for automated defect characterization systems in which porosity, cracks, and dross have been distinguished. Because of the requirement to scan the probe over the surface, the application of B-scan and C-scan methods has generally been limited to simple geometric shapes having good surface finish, such as welded plate structures. Application to castings is currently restricted, but greater use of B-scan and C-scan methods is likely with either improved scanning systems or arrays of ultrasonic probes.

Structure evaluation is an area of growing importance for foundry engineers. Ultrasonic velocity measurements are widely used as a means of guaranteeing the nodularity of the graphite structure and, if the matrix structure is known to be consistent, guaranteeing the principal material properties of ductile irons (Ref 1). Velocity measurements have been used to evaluate compacted graphite iron structures to ensure that the desired properties have been consistently obtained. The use of ultrasonic velocity measurements for structure evaluation is discussed in the section "Ductile Iron Castings" in this article.

Nondestructive Inspection of Castings

By the ASM Committee on Nondestructive Inspection of Castings*

Leak Testing

Castings that are intended to withstand pressures can be leak tested in the foundry. Various methods are used, according to the type of metal being tested (see the article "Leak Testing" in this Volume). One method consists of pumping air at a specific pressure into the inside of the casting in water at a given temperature. Any leaks through the casting become apparent by the release of bubbles of air through the faulty portions. An alternative method is to fill the cavities of a casting with paraffin at a specified pressure. Paraffin, which penetrates the smallest of crevices, will rapidly find any defect, such as porosity, and will show quickly as an oily or moist patch at the position of the fault. Liquid penetrants can be poured into areas of apparent porosity and time allowed for the liquid to seep through the casting wall.

The pressure testing of rough (unmachined) castings at the foundry may not reveal any leaks, but it must be recognized that subsequent machining operations on the casting may cut into porous areas and cause the casting to leak after machining. Minor seepage leaks can be sealed by impregnation of the casting with liquid or by filling with sodium silicate, a synthetic resin, or other suitable substance. As-cast parts can be impregnated at the foundry to seal leaks if there is to be little machining or if experience has shown that machining does not affect the pressure tightness. However, it is usually preferable to impregnate after final machining of the casting.

Nondestructive Inspection of Castings

By the ASM Committee on Nondestructive Inspection of Castings*

Inspection of Ferrous Castings

Ferrous castings can be inspected by most of the nondestructive inspection methods. Magnetic particle inspection can be applied to ferrous metals with excellent sensitivity, although a crack in a ferrous casting can often be seen by visual inspection. Magnetic particle inspection provides good crack delineation, but the method should not be used to detect other defects. Nonrelevant magnetic particle indications occasionally occur on ferrous castings, especially with a strong magnetic field. For example, a properly fused-in steel chaplet can be indicated as a defect because of the difference in magnetic response between low-carbon steel and cast iron. Even the graphite in cast iron, which is nonmagnetic, can cause a nonrelevant indication. Standard x-ray and radioactive-source techniques can be used to make radiographs of ferrous castings, but the typical complexity of shape and varying section thicknesses of the castings may require digital radiography or computed tomography.

Ultrasonic inspection for both thickness and defects is practical with most ferrous castings except for the high-carbon gray iron castings, which have a high damping capacity and absorb much of the input energy. The measurement of resonant frequency is a good method of inspecting some ductile iron castings for soundness and graphite shape. Electromagnetic testing can be used to distinguish metallurgical differences between castings. The criteria for separating acceptable from unacceptable castings must be established empirically for each casting lot.

Gray Iron Castings

Gray iron castings are susceptible to most of the imperfections generally associated with castings, with additional problems resulting from the relatively high pouring temperatures. These additional problems result in a higher incidence of gas entrapment, inclusions, poor metal structure, interrupted metal walls, and mold wall deficiencies.

Gas entrapment is a direct result of gas being trapped in the casting wall during solidification. This gas may be in the metal prior to pouring, may be generated from aspiration during pouring, or may be generated from core and mold materials. Internal defects of this type are best detected by radiography, but ultrasonic and eddy current inspection methods are useful when the defect is large enough to be detected by these methods.

Inclusions are casting defects in which solid foreign materials are trapped in the casting wall. The inclusion material can be slag generated in the melting process, or it can be fragments of refractory, mold sand, core aggregate, or other materials used in the casting process. Inclusions appear most often on the casting surface and are usually detected by visual inspection, but in many cases the internal walls of castings contain inclusions that cannot be visually detected. Internal inclusions can be detected by eddy current, radiographic, or ultrasonic inspection; radiography is usually the most reliable method.

Poor Metal Structure. Many casting defects resulting from metal structure are related to shrinkage, which is either a cavity or a spongy area linked with dendrites or a depression in the casting surface. This type of defect arises from varying rates of contraction while the metal is changing from a liquid to a solid. Other casting defects resulting from varying rates of contraction during solidification include carbide formation, hardness variations, and microporosity.

Internal shrinkage defects are best detected by radiography, although eddy current or ultrasonic inspection can be used. Soft or hard gray iron castings are usually detected by Brinell hardness testing; electromagnetic methods have proved useful on some castings.

Interrupted Metal Walls. Included in this category are such flaws as hot tears, cold shuts, and casting cracks. Cracking of castings is often a major problem in gray iron foundries because of the combination of casting designs and high production rates. Visual inspection or an aided visual method such as liquid penetrant or magnetic particle inspection is used to detect cracks and cracklike flaws in castings.

Mold wall deficiencies are common problems in gray iron castings. They result in surface flaws such as scabs, rattails, cuts, washes, buckles, drops, and excessive metal penetration into the spaces between sand grains. These flaws are generally detected by visual inspection.

Size and Quantity of Graphite. In cast iron, the length of the lamellae (flakes)--that is, the coarseness of the graphite--is expressed by code numbers from 1 to 8, as described in ASTM A 247 and in *Casting*, Volume 15 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*. These numbers correspond to lamellar lengths ranging from 1.25 to 0.01 mm (0.05 to 0.0004 in.), as viewed in micrographs of the cast iron structure. The dependence of the longitudinal wave sonic velocity on the size and quantity of graphite is shown in Fig. 15; with decreasing coarseness and quantity of graphite, the velocity approaches that in steel. In microlamellar cast iron, the amount of graphite is usually smaller. Therefore, the finer the graphite, the higher the sonic velocity. In both lamellar and spheroidal cast irons, the transverse wave sonic velocity is related to the longitudinal wave velocity, as shown in Fig. 16.

Fig. 15 Variation of longitudinal wave sonic velocity with graphite size for lamellar cast iron containing different percentages of free graphite. Scale at right indicates ratio of sonic velocity in cast iron to corresponding sonic velocity in steel.

Fig. 16 Relation of longitudinal wave and transverse wave sonic velocities for spheroidal and lamellar cast irons and for steel

Malleable Iron Castings

Blowholes and spikes are defects often found in malleable iron castings. Spikes are a form of surface shrinkage not normally visible to the naked eye, but they appear as a multitude of short, discontinuous surface cracks when subjected to fluorescent magnetic particle inspection. Unlike true fractures, spikes do not propagate, but they are not acceptable where cyclic loading could result in fatigue failure. Spikes are usually seen as short indications about 1.6 mm ($\frac{1}{16}$ in.) long or less and never more than 75 μm (0.003 in.) deep. These defects do not have a preferred orientation, but a random pattern that may or may not follow the direction of solidification. Shrinkage or open structure in the gated area is a defect often found in malleable iron castings that may be overlooked by visual inspection, although it is readily detected by either liquid penetrant or magnetic particle inspection.

Ductile Iron Castings

Ductile iron is cast iron in which the graphite is present in tiny balls or spherulites instead of flakes (as in gray iron) or compacted aggregates (as in malleable iron). The spheroidal graphite structure is produced by the addition of one or more elements to the molten metal.

Soundness and Integrity. Cracks and fine tears that break the surface of the casting but are difficult to detect visually can be revealed with dye penetrants or magnetic particle inspection. Modern techniques of magnetizing the casting, followed by the application of fluorescent magnetic inks, are very effective and widely used.

Methods of sonic testing that involve vibrating the casting and noting electronically the rate of decay of resonant frequency or damping behavior are also used to detect cracked or flawed castings. Internal unsoundness, when not immediately subsurface, can be detected with ultrasonic inspection by the failure to observe a back wall echo when using reflected radiation or by a weakening of the signal in the transmission through the casting. Coupling of the probes and interpretation of the results involve operator skill, but methods are available that consist of partial or total immersion of the casting in a liquid, automatic or semiautomatic handling of the probes, and computer signal processing to ensure more reliable and consistent interpretation of results. Problems arise in detecting very-near-surface defects and when examining thin castings, but the use of angled probes and shear wave techniques has yielded good results.

The soundness of the ductile iron can also be assessed by x-ray or γ -ray examination. The presence of graphite, especially in heavy sections, makes the method more difficult to evaluate than for steels, but the use of image intensification by electronic means offers considerable promise, especially for sections up to 50 mm (2 in.) thick.

Confirmation of Graphite Structure (Ref 4). Both the velocity of ultrasonic transmission and the resonant frequency of a casting can be related to the modulus of elasticity. In cast iron, the change from flake graphite to nodular graphite is related to an increase in both modulus of elasticity and strength; therefore, ultrasonic velocity or resonant frequency measurement can be employed as a guide to modularity, strength, and other related properties. Because the microscopic estimation of nodularity is a subjective measurement, these other nondestructive examination methods may provide a better guide to some properties provided the matrix remains constant (Ref 5). Figure 17 illustrates how ultrasonic velocity may vary with graphite nodularity.

Fig. 17 Ultrasonic velocity versus visually assessed modularity in ductile iron castings

Ultrasonic transmission measurement is conducted with two probes on either side of the casting. This method provides a guide to the local properties. It must be coupled with a thickness measurement, and automatic equipment is commonly used, often involving immersion of the casting in a tank of fluid (Fig. 18). The calculation does not require calibration of the castings. Simple caliper devices have also been used for examining castings and simultaneously measuring their thickness to provide a calculated value of ultrasonic velocity and a guarantee of modularity (Ref 6).

Fig. 18 Ultrasonic test equipment used for determining the thickness, nodularity, and integrity of ductile iron castings. (a) Schematic of setup for the ultrasonic velocity testing for structure evaluation. (b) Photograph of test instrument used for integrity/nodularity studies showing controls and instrumentations. Courtesy of J. Johnston, Krautkramer Branson

Sonic testing involves measurement of the resonant frequency of the casting or rate of decay of resonance of a casting that has first been excited by mechanical or electrical means. This method evaluates the graphite structure of the entire casting and requires calibration of the castings against standard castings of known structure. It is also necessary to maintain casting dimensions within a well-controlled narrow range. Some foundries use sonic testing as a routine method of final inspection and structure guarantee (Ref 7).

The relationship between modularity, resonant frequency, or ultrasonic transmission velocity and properties has been documented for tensile strength, proof strength, fatigue, and impact strength. Examples are shown in Fig. 19 and 20.

Fig. 19 Ultrasonic velocity versus strength in ductile iron castings

Fig. 20 Strength versus resonant frequency in the nondestructive evaluation of ductile iron test bars

The presence of carbides can also be detected with sonic or ultrasonic measurements provided enough carbides are present to reduce the graphite sufficiently to affect the modulus of elasticity. Discrimination between the effects of graphite variation and carbide amount would require an additional test, such as a hardness test.

Properties Partially Dependent on Graphite Structure (Ref 7). When the matrix structure of ductile iron varies, this variation cannot be detected as easily as variations in graphite structure, and sonic and ultrasonic readings may not be able to reflect variations in mechanical properties. A second measurement, such as a hardness measurement, is then needed to detect matrix variations in the same way as would be necessary to confirm the presence of carbides.

Eddy current or coercive force measurements can be used to detect many changes in casting structure and properties; but the indications from such measurements are difficult to interpret, and the test is difficult to apply to many castings unless they are quite small and can be passed through a coil 100 to 200 mm (4 to 8 in.) in diameter. Eddy current indications are, however, useful for evaluating pearlite and carbide in the iron matrix. Multifrequency eddy current testing uses probes that do not require the casting to pass through a coil, it is less sensitive to casting size, and it allows automatic measurements and calculations to be made; but the results remain difficult to interpret with reliability in all cases. It may, however, be a very good way to detect chill and hard edges on castings of reproducible dimensions.

Nondestructive Inspection of Castings

By the ASM Committee on Nondestructive Inspection of Castings*

Inspection of Aluminum Alloy Castings

Effective quality control is needed at every step in the production of an aluminum alloy casting, from selection of the casting method, casting design, and alloy to mold production, foundry technique, machining, finishing, and inspection. Visual methods, such as visual inspection, pressure testing, liquid penetrant inspection, ultrasonic inspection, radiographic inspection, and metallographic examination, can be used to inspect for casting quality. The inspection procedure used should be geared toward the specified level of quality. Information on casting processes, solidification, hydrogen content, silicon modification, grain refinement, and other topics related to aluminum alloy castings is provided in the articles "Solidification of Eutectic Alloys: Aluminum-Silicon Alloys," "Nonferrous Molten Metal Processes," and "Aluminum and Aluminum Alloys" in *Casting*, Volume 15 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*.

Stages of Inspection. Inspection can be divided into three stages: preliminary, intermediate, and final. After tests are conducted on the melt for hydrogen content, for adequacy of silicon modification, and for degree of grain refinement, preliminary inspection may consist of the inspection and testing of test bars cast with the molten alloy at the same time the production castings are poured. These test bars are used to check the quality of the alloy and the effectiveness of the heat treatment. Preliminary inspection also includes chemical or spectrographic analysis of the casting, thus ensuring that the melting and pouring operations have resulted in an alloy of the desired composition.

Intermediate inspection, or hot inspection, is performed on the casting as it is taken from the mold. This step is essential because castings that are obviously defective can be discarded at this stage of production. Castings that are judged unacceptable at this stage can then be considered for salvage by impregnation, welding, or other methods, depending on

the type of flaw present and the end use of the casting. More complex castings usually undergo visual and dimensional inspection after the removal of gates and risers.

Final inspection establishes the quality of the finished casting through the use of any of the methods previously mentioned. Visual inspection also includes the final measurement and comparison of specified and actual dimensions. Dimensions of castings from a large production run can be checked with gages, jigs, fixtures, or coordinate measuring systems.

Liquid penetrant inspection is extensively used as a visual aid for detecting surface flaws in aluminum alloy castings. Liquid penetrant inspection is applicable to castings made from all the aluminum casting alloys as well as castings produced by all methods. One of the most useful applications, however, is the inspection of small castings produced in permanent molds from alloys such as 296.0, which are characteristically susceptible to hot cracking. For example, in cast connecting rods, hot shortness may result in fine cracks in the shank sections. Such cracks are virtually undetectable by unaided visual inspection, but are readily detectable by liquid penetrant inspection.

All the well-known liquid penetrant systems (that is, water-washable, postemulsifiable, and solvent-removable) are applicable to the inspection of aluminum alloy castings. In some cases, especially for certain high-integrity castings, more than one system can be used. Selection of the system is primarily based on the size and shape of the castings, surface roughness, production quantities, sensitivity level desired, and available inspection facilities.

Pressure testing is used for castings that must be leaktight. Cored-out passages and internal cavities are first sealed off with special fixtures having air inlets. These inlets are used to build up the air pressure on the inside of the casting. The entire casting is then immersed in a tank of water, or it is covered by a soap solution. Bubbles will mark any point of air leakage.

Radiographic inspection is a very effective means of detecting such conditions as cold shuts, internal shrinkage, porosity, core shifts, and inclusions in aluminum alloy castings. Radiography can also be used to measure the thickness of specific sections. Aluminum alloy castings are ideally suited to examination by radiography because of their relatively low density; a given thickness of aluminum alloy can be penetrated with about one-third the power required for penetrating the same thickness of steel.

Aluminum alloy castings are most often radiographed with an x-ray machine, using film to record the results. Real-time (digital) radiography and computed tomography are also widely used and are best suited to detecting shrinkage, porosity, and core shift (Fig. 12 and 13). Gamma-ray radiography is also satisfactory for detecting specific conditions in aluminum castings. Although the γ -ray method is used to a lesser extent than the x-ray method, it is about equally as effective for detecting flaws or measuring specific conditions. Aluminum alloy castings are most often radiographed to detect approximately the same types of flaws that may exist in other types of castings, that is, conditions such as porosity or shrinkage, which register as low-density spots or areas and appear blacker on the film or real-time image screen than the areas of sound metal.

Aluminum ingots may contain hidden internal cracks of varying dimensions. Depending on size and location, these cracks may cause an ingot to split during mechanical working and thermal treatment, or they may appear as a discontinuity in the final wrought product. Once the size and location of such cracks are determined, an ingot can be scrapped, or sections free from cracks can be sawed out and processed further. Because the major dimensions of the cracks are along the casting direction, they present good reflecting surfaces for sound waves traveling perpendicular to the casting direction. Therefore, ultrasonic methods using a wave frequency that gives adequate penetration into the ingot provide excellent sensitivity for 100% inspection of that part of the ingot containing critical cracks. Because of ingot thickness (up to 400 mm, or 16 in.) and the small metal separation across the crack, radiographic methods are impractical for inspection.

Ultrasonic Inspection. Aluminum alloy castings are sometimes inspected by ultrasonic methods to evaluate internal soundness or wall thickness. The principal uses of ultrasonic inspection for aluminum alloy castings include the detection of porosity in castings and internal cracks in ingots.

Nondestructive Inspection of Castings

By the ASM Committee on Nondestructive Inspection of Castings*

Inspection of Copper and Copper Alloy Castings

The inspection of copper and copper alloy castings is generally limited to visual and liquid penetrant inspection of the surface, along with radiographic inspection for internal discontinuities. In specific cases, electrical conductivity tests and ultrasonic inspection can be applied, although the usual relatively large cast grain size could prevent a successful ultrasonic inspection.

Visual inspection is simple yet informative. A visual inspection would include significant dimensional measurements as well as general appearance. Surface discontinuities often indicate the presence of internal discontinuities.

For small castings produced in reasonable volume, a destructive metallographic inspection on randomly selected samples is practical and economical. This is especially true on a new casting for which foundry practice has not been optimized and a satisfactory repeatability level has not been achieved.

For castings of some of the harder and stronger alloys, a hardness test is a good means of estimating the level of mechanical properties. Hardness tests are of less value for the softer tin bronze alloys because hardness tests do not reflect casting soundness and integrity.

Because copper alloys are nonmagnetic, magnetic particle inspection cannot be used to detect surface cracks. Instead, liquid penetrant inspection is recommended. Ordinarily, liquid penetrant inspection requires some prior cleaning of the casting to highlight the full detail.

For the detection of internal defects, radiographic inspection is recommended. Radiographic methods and standards are well established for some copper alloy castings (for example, ASTM E 272 and E 310).

As a general rule, the method of inspection applied to some of the first castings made from a new pattern should include all those methods that provide a basis for judgment of the acceptability of the casting for the intended application. Any deficiencies or defects should be reviewed and the degree of perfection defined. This procedure can be repeated on successive production runs until repeatability has been ensured.

Gas Porosity. Copper and many copper alloys have a high affinity for hydrogen, with an increasing solubility as the temperature of the molten bath is increased. Conversely, as the metal cools in the mold, most of this hydrogen is rejected from the metal. Because all the gas does not necessarily escape to the atmosphere and may become entrapped by the solidifying process, gas porosity may be found in the casting.

In most alloys, gas porosity is identified by the presence of voids that are relatively spherical and are bright and shiny inside. Visible upon sectioning or by radiography, they may either be small, numerous, and rather widely dispersed or fewer in number and relatively large. Regardless of size, they are seldom interconnected except in some of the tin bronze alloys, which solidify in a very dendritic mode. In these alloys, the gas porosity tends to be distributed in the interstices between the dendrites.

Shrinkage voids caused by the change in volume from liquid to solid in copper alloys are different only in degree and possibly shape from those found in other metals and alloys. All nonferrous metals exhibit this volume shrinkage when solidifying from the molten condition.

Shrinkage voids may be open to the air when near or exposed to the surface, or they may be deep inside the thicker sections of the casting. They are usually irregular in shape, compared to gas-generated defects, in that their shape frequently reflects the internal temperature gradients induced by the external shape of the casting.

Hot Tearing. The tin bronzes as a class, as well as a few of the leaded yellow brasses, are susceptible to hot shortness; that is, they lack ductility and strength at elevated temperature. This is significant in that tearing and cracking can take place during cooling in the mold because of mold or core restraint. In aggravated instances, the resulting hot tears in the

part appear as readily visible cracks. Sometimes, however, the cracks are not visible externally and are not detectable until after machining. In extreme cases, the cracks become evident only through field failure because the tearing was deep inside the casting.

Nonmetallic inclusions in copper alloys, as with all molten alloys, are normally the result of improper melting and/or pouring conditions. In the melting operation, the use of dirty remelt or dirty crucibles, poor furnace linings, or dirty stirring rods can introduce nonmetallic inclusions into the melt. Similarly, poor gating design and pouring practice can produce turbulence and can generate nonmetallic inclusions. Sand inclusions may also be evident as the result of improper sand and core practice. All commercial metals, by the nature of available commercial melting and molding processes, usually contain very minor amounts of small nonmetallic inclusions. These have little or no effect on the casting. Inclusions of significant size or number are considered detrimental. A thorough review of copper alloy melting, refining, and casting practices is available in *Casting*, Volume 15 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*.

Nondestructive Inspection of Powder Metallurgy Parts

R.C. O'Brien and W.B. James, Hoeganaes Corporation

Introduction

THE PROBLEM of forming defects in green parts during compaction and ejection has become more prevalent as parts producers have begun to use higher compaction pressures in an effort to achieve high-density, high-performance powder metallurgy (P/M) steels. In this article, several nondestructive inspection methods are evaluated, with the aim of identifying those that are practical for detecting defects as early as possible in the production sequence.

The most promising nondestructive testing methods for P/M applications include electrical resistivity testing, eddy current and magnetic bridge testing, magnetic particle inspection, ultrasonic testing, x-ray radiography, gas permeability testing, and γ -ray density determination. The capabilities and limitations of each of the techniques are evaluated in this article.

Nondestructive Inspection of Powder Metallurgy Parts

R.C. O'Brien and W.B. James, Hoeganaes Corporation

Current Status of P/M Testing

In the ceramics industry, the fraction of the finished-part cost that arises from scrap due to flaws introduced during processing is estimated to average 50%, and it can be as high as 75% (Ref 1). Although the ceramics industry has been mobilized for the past 15 years toward the use of nondestructive evaluation in processing, the P/M industry has built up only a scattered background of experience (Ref 2).

To remain competitive, P/M parts producers have increasingly turned to simplified processing. It has been shown that the physical properties of P/M parts, especially the fatigue strength, are always improved by increasing the density (Ref 3). The need for densification by double pressing can often be avoided by pressing to high density in a single step. However, the use of higher compaction pressures requires the utmost attention to materials selection, tool design, and press setup (Ref 4). A quick, preferably nondestructive method of crack detection would be of great benefit during press setup and for testing the integrity of parts as early as possible in their production sequence.

The growth of nondestructive testing in the 1980s has been explosive, and the field has benefited greatly from computerized image reconstruction techniques applied to radiography, ultrasonic, and even magnetic particle inspection. Commercial test systems are being marketed as fast as the technology is developed, and the metal powder industry should find solutions to its on-line testing needs by reviewing methods being used by other parts fabrication technologies.

In preparing this article, a number of test methods presented themselves as having potential for crack detection in green (unsintered) P/M compacts, and these are recommended for further investigation. For a detailed overview of P/M technology, the reader is referred to *Powder Metal Technologies and Applications*, Volume 7 of the *ASM Handbook*.

Summary of Defect Types in P/M Parts

The four most common types of defects in P/M parts are ejection cracks, density variations, microlaminations, and poor sintering.

Ejection Cracks. When a part has been pressed, there is a large residual stress in the part due to the constraint of the die and punches, which is relieved as the part is ejected from the die. The strain associated with this stress relief depends on the compacting pressure, the green expansion of the material being compacted, and the rigidity of the die. Green expansion, also known as spring out, is the difference between the ejected-part size and the die size. A typical value of green expansion for a powder mix based on atomized iron powder pressed at relatively high pressure (600 to 700 MPa, or 45 to 50 tsi) is 0.20%. In a partially ejected compact, for example, the portion that is out of the die expands to relieve the residual stress, while the constrained portion remains die size and a shear stress is imposed on the compact. When the ability of the powder compact to accommodate the shear stress is exceeded, ejection cracks such as the one shown in Fig. 1 are formed.

Fig. 1 Ejection crack in sintered P/M steel. Unetched

The radial strain can be alleviated to a degree by increasing the die rigidity and designing some release into the die cavity. However, assuming that the ejection punch motions are properly coordinated, the successful ejection of multilevel parts depends to a large degree on the use of a high-quality powder that combines high green strength with low green expansion and low stripping pressure.

introduction of a step or second level in the part. Depending on the severity of the step, a separate, independently actuated punch can be required for each level of the part. During the very early stage of compaction, the powder redistributes itself by flowing between sections of the die cavity. However, when the pressure increases and the powder movement is restricted, shearing of the compact in planes parallel to the punch axis can only be avoided by proper coordination of punch motions. When such shear exists, a density gradient results.

The density gradient is not always severe enough for an associated crack to form upon ejection. However, a low-density area around an internal corner, as shown in Fig. 2, can be a fatal flaw, because this corner is usually a point of stress concentration when the part is loaded in service.

Fig. 2 Density gradient around an internal corner in a part made with a single-piece stepped punch. Unetched

Microlaminations. In photomicrographs of unetched part cross sections, microlaminations such as those shown in Fig. 3 appear as layers of unsintered interparticle boundaries that are oriented in planes normal to the punch axis. They can be the result of fine microcracks associated with shear stresses upon ejection; such microcracks fail to heal during sintering. Because of their orientation parallel to the tensile axis of standard test bars, they have little influence on the measured tensile properties of the bars, but are presumed to be a cause of severe anisotropy of tensile properties.

Fig. 3 Microlaminations in sintered P/M steel. Unetched

Poor Sintering. When unsintered particle boundaries result from a cause other than shear stresses, they are usually present because of insufficient sintering time or sintering temperature, a nonreducing atmosphere, poor lubricant burn-off, inhibition of graphite dissolution, or a combination of these. A severe example is shown in Fig. 4. Unlike microlaminations, defects associated with a poor degree of sintering are not oriented in planes.

Fig. 4 Poor degree of sintering in P/M compact. Unetched

Nondestructive Inspection of Powder Metallurgy Parts

R.C. O'Brien and W.B. James, Hoeganaes Corporation

Nondestructive Tests and Their Applicability to P/M Processing

As described below, applicable inspection methods for P/M parts can be broadly classified into the following categories:

- Radiographic techniques
- Acoustic methods

- Thermal inspection
- Electrical resistivity inspection
- Visual inspection and pressure testing

The techniques covered in this article are summarized in Table 1. Additional information on these procedures can be found in the Section "Methods of Nondestructive Evaluation" in this Volume.

Table 1 Comparison of the applicability of various nondestructive evaluation methods to flaw detection in P/M parts

Method	Measured/detected	Applicability to P/M parts ^(a)		Advantages	Disadvantages
		Green	Sintered		
X-ray radiography	Density variations, cracks, inclusions	C	C	Can be automated	Relatively high initial cost; radiation hazard
Computed tomography	Density variations, cracks, inclusions	C	C	Can be automated; pinpoint defect location	Extremely high initial cost; highly trained operator required; radiation hazard
Gamma-ray density determination	Density variations	A	A	High resolution and accuracy; relatively fast	High initial cost; radiation hazard
Ultrasonic imaging: C-scan	Density variations, cracks	D	B	Sensitive to cracks; fast	Coupling agent required
Ultrasonic imaging: SLAM	Density variations, cracks	D	C	Fast; high resolution	High initial cost; coupling agent required
Resonance testing	Overall density, cracks	D	B	Low cost; fast	Does not give information on defect location
Acoustic emission	Cracking during pressing and ejection	C	D	Low cost	Exploratory
Thermal wave imaging	Subsurface cracks, density variations	D	C	No coupling agent required	Flat or convex surfaces only
Electrical resistivity	Subsurface cracks, density variations, degree of sinter	A	A	Low cost, portable, high potential for use on green compacts	Sensitive to edge effects
Eddy current/magnetic bridge	Cracks, overall density, hardness, chemistry	C	A	Low cost, fast, can be automated; used on P/M valve seat inserts	Under development;

Magnetic particle inspection	Surface and near-surface cracks	C	A	Simple to operate, low cost	Slow; operator sensitive
Liquid dye penetrant inspection	Surface cracks	C	D	Low cost	Very slow; cracks must intersect surface
Pore pressure rupture/gas permeability	Laminations, ejections, cracks, sintered density variations	A	A	Low cost, simple, fast	Gas-tight fixture required; cracks in green parts must intersect surface

(a) A, has been used in the production of commercial P/M parts; B, under development for use in P/M; C, could be developed for use in P/M, but no published trials yet; D, low probability of successful application to P/M

Radiographic Techniques

X-Ray Radiography. Any feature of a part that either reduces or increases x-ray attenuation will be resolvable by x-ray radiography. Some types of flaws and their x-ray images are shown in Fig. 5.

Fig. 5 Schematic of flaws and their x-ray images. Defect types that can be detected by x-ray radiography are those that change the attenuation of the transmitted x-rays. Source: Ref 6

The ability to detect defects depends on their orientation to the x-ray source. A crack parallel to the x-rays will result in reduced attenuation of the rays, and the x-ray film will be darker in this region. A thin crack perpendicular to the x-ray will hardly influence attenuation and will not be detected.

Historically, flaw detection by x-ray radiography has been an expensive and cumbersome process suited only to safety-critical and high added value parts. The process has been considerably improved by the development of real-time imaging techniques that replace photographic film. Real-time imaging means that parts can be tested rapidly and accepted or rejected on the spot.

Real-time x-ray systems include image intensifiers or screens that convert x-rays into visible light and discrete detector arrays that convert x-rays into electronic signals (which are reconstructed by computer for video display). The image in all these systems can be recorded and digitized for image enhancement. The ability of the system to detect flaws is, however, still sensitive to defect orientation. Additional information is available in the article "Radiographic Inspection" in this Volume.

Computed tomography is a recently developed version of x-ray radiography that includes highly sophisticated analysis of the detected radiation. A tomographic setup consists of a high-energy photon source, a rotation table for the specimen, a detector array, and the associated data analysis and display equipment, as shown in Fig. 6. The ability to rotate the specimen increases the chance of orienting a defect relative to the x-rays such that it will be detected. The x-ray source and detector array can be raised or lowered to examine different planes through the sample.

Fig. 6 Schematic of computed tomography, which is the reconstruction by computer of a series of tomographic planes (slices) of an object. The transmitted intensity of the fan-shaped beam is processed by computer and the resulting image is displayed on a terminal. Source: Ref 7

In a typical system, the photon source can be a radioisotope such as ^{60}Co , depending on the energy requirements of the individual specimens. The lead aperture around the source acts as a collimator to produce a fan-shaped beam about 5 mm (0.2 in.) thick. The sample is rotated in incremental steps, and the transmitted radiation is detected at each step by computer-controlled detectors situated one every 14 mm (0.55 in.) in a two-dimensional array.

The computer then reconstructs the object using intensity data from a number of scans at different orientations. The output is in the form of a two-dimensional plan in which colors are mapped onto the image according to the intensity of the transmitted radiation. The resolution available depends on the difference in density between the various features of the object. For example, steel pins embedded in polyvinyl chloride plastic are more easily resolvable than aluminum pins of the same diameter (Ref 7). Experiments with P/M samples have shown that density can be measured to better than 1% accuracy, with a spatial resolution of 1 mm (0.04 in.) (Ref 8). The article "Industrial Computed Tomography" in this Volume contains more information on the principles and applications of this technique.

Gamma-Ray Density Determination. Local variations in the density of P/M parts have been detected by measuring the attenuation of γ -rays passing through the part (Ref 9). Depending on the material and the dimensions of the part, density can be measured to an accuracy of ± 0.2 to $\pm 0.7\%$, and the technique has been used by P/M parts fabricators in place of immersion density tests as an aid in tool setting.

The apparatus consists of a vertically collimated γ -ray beam originating from a radioisotope. The beam passes through the sample as shown in Fig. 7 and reaches a detector via a 1 mm (0.04 in.) diam aperture, where the transmitted intensity is measured. The detector consists of a sodium iodide scintillation crystal, which in turn excites a photomultiplier. Exposure time is 1 to 2 min; a 4 mm (0.15 in.) aperture can reduce this time to 30 s at the expense of some resolution. The radiation source of the Gamma Densomat is Americium 241 (60 keV). For high-energy beams, Cesium 137 (660 keV) can be substituted.

Fig. 7 Schematic of the Gamma Densomat. Source: Ref 9

This method has been shown to be particularly useful in cases where the section of the part to be checked is too small for immersion density measurements (Ref 10). Tool life was extended when the method was used for part density checks in order to avoid overloading.

Acoustic Methods

Ultrasonic Testing. Many characteristics of solids can be determined from the behavior of sound waves propagating in them. Ultrasonic signals impinged on a sample at one surface are transmitted at speeds and attenuated at rates determined by the density, modulus of elasticity, and continuity of the material. The sound waves are reflected from other surfaces of the sample, including cracks as well as free surfaces. They can be picked up and amplified for display on a CRT screen, as described in Ref 6 and the article "Ultrasonic Inspection" in this Volume. The height and position of the flaw/defect peak indicate its size and location. Although much effort has been directed toward relating sound propagation to the physical properties of P/M materials, little has been written on the detection of cracks by the ultrasonic inspection of porous materials.

Ultrasound Transmission in Green Compacts. The characterization of green compacts by ultrasonic techniques appears to be hindered by problems of extreme attenuation of the incident signal. In one case, signals of 1 to 20 MHz were transmitted through an 8 mm (0.3 in.) thick compact of atomized iron with 0.2% graphite added (Ref 11). Although the attenuation did not allow back-wall echo measurement, through-transmission measurements indicated that the transmitted intensity had a maximum at 4 to 5 MHz (Fig. 8). Density was found to influence the transmitted intensity, with specimens at 95% relative density allowing some degree of transmission over the entire range of frequencies tested, while specimens at 87% relative density damped the incident signals entirely.

Fig. 8 Ultrasonic spectrum analyzer output showing change in transmitted intensity with density of green compact. Source: Ref 11

Figure 9 shows that the velocity of ultrasonic waves in green compacts is about half the velocity in sintered compacts and that it is essentially invariant with density (Ref 13). It has also been shown that the velocity of ultrasound in green parts is highly anisotropic and that the experimental reproducibility is very poor (Fig. 10). It has been proposed that the anisotropy in velocity is due to the orientation of porosity (Ref 15).

Fig. 9 Effect of density on ultrasonic velocity in green and sintered cylindrical Ancorsteel 1000-B specimens.
Source: Ref 12

Fig. 10 Anisotropy of ultrasound in green transverse rupture strength bars. Source: Ref 14

The variation in the velocity of ultrasound with applied pressure during the compaction of ceramic powders has been measured *in situ* by fixing transducers to the ends of the punches (Ref 16). Unlike the case of finished green P/M compacts, a clear relationship was found between longitudinal wave velocity and compacting pressure (Fig. 11), probably because the constraint of the punches and die forced the individual particles together, providing an efficient acoustic coupling between particles.

Fig. 11 Ultrasonic wave velocity in ceramic powders, measured during compaction. Source: Ref 16

Ultrasound Transmission in Sintered Parts. Early work relating the physical properties of cast iron to the velocity of sound waves suggested the potential for evaluating P/M steels in the same way (Ref 17). As expected, both the velocity of sound in P/M parts and their resonant frequencies have been related to density, yield strength, and tensile strength. Plain carbon steel P/M specimens were used in one series of tests and the correlation was found to be close enough for the test to be used as a quick check for the degree of sintering in production P/M parts (Ref 12). Other work has demonstrated the relationship between sound velocity and tensile strength in porous parts (Fig. 12). The same types of relationships have also been documented in powder forgings Ref 19.

Fig. 12 Correlation of ultrasonic velocity with tensile strength of sintered steel. Source: Ref 18

Sintered parts have been found to transmit ultrasound according to the relationships shown in Fig. 13. The highest wave velocities occurred in the pressing direction. An additional distinction was found between the velocities in the longitudinal and lateral axes of an oblong specimen, and these results were shown to be reproducible between different powder lots and specimen groups. The anisotropy of velocity diminished at higher densities and disappeared above 6.85 g/cm³.

Fig. 13 Anisotropy of ultrasound velocity in sintered transverse rupture strength bars. Source: Ref 14

Ultrasonic Imaging: C-Scan. The C-Scan is a form of ultrasonic testing in which the testpiece is traversed by the ultrasound transducer in a computer-controlled scan protocol (Fig. 14). The transmitted intensity is recorded and analyzed by computer, and a gray-mapped image is output.

Fig. 14 Schematic of a C-Scan scanning protocol for an adhesive-bonded structure. Source: Ref 20

In one trial, seeded oxide inclusions were detected in porous sintered steels using a C-Scan (Ref 21). The inclusions consisted of admixed particles of chromium oxide and alumina at concentrations of 65 to 120 particles per square centimeter. Inclusions as small as 50 μm in diameter were detected. Additional information on the C-Scan can be found in the articles "Ultrasonic Inspection" and "Adhesive-Bonded Joints" in this Volume.

Ultrasonic Imaging: Scanning Acoustic Microscopy (SAM). Ultrasonic waves can be focused on a point using a transducer and lens assembly, as shown in Fig. 15 and described in the article "Acoustic Microscopy" in this Volume. In this way, the volume of the specimen being examined is highly limited, so that reflections from defects can be closely located at a given depth and position in the specimen. In SAM, the specimen is moved by stepper motors in a raster pattern, and an image of the entire structure can be built up. Scanning acoustic microscopy has been shown to be capable of resolving small surface and subsurface cracks, inclusions, and porosity in sintered, fully dense ceramics (Ref 22).

Fig. 15 Schematic of the image-forming process in scanning acoustic reflecting microscopy. Source: Ref 22

Ultrasonic Imaging: Scanning Laser Acoustic Microscopy (SLAM). When a continuous plane wave impinges on a sample that is roughly flat in shape, it propagates through and is emitted from the sample with relatively little scattering, retaining its planar nature. When the plane wave is emitted from the sample, it contains information on variations in properties that were encountered in the interior of the sample, which takes the form of variations in intensity with position in the plane. A scanning laser acoustic microscope detects these variations as distortions in a plastic sheet that is placed in the path of the plane wave. The information is gathered by a laser that scans a reflective coating on one side of the sheet, as shown in Fig. 16 and explained in the article "Acoustic Microscopy" in this Volume.

Fig. 16 General configuration used in scanning laser acoustic microscopy. Source: Ref 23

Therefore, although ultrasonic testing is not appropriate for evaluating green P/M parts, it is applicable to the assessment of sintered components. Optimum results dictate careful selection and placement of the transducers because the orientation of the defects influences the ability to detect them. Small defects close to the specimen surface can be masked by surface echoes. Although enhanced image analysis techniques appear beneficial, it is unlikely that the more sophisticated techniques, such as C-Scan and SLAM, will be cost effective for most ferrous P/M parts in the near future.

Resonance Testing. When a structural part is tapped lightly, it responds by vibrating at its natural frequency until the sound is damped. Both the damping characteristics and the natural frequency change with damage to the structure. Changes in the natural frequency can be detected with a spectrum analyzer, as shown in Fig. 17.

Fig. 17 Schematic of resonance test configuration. Source: Ref 24

Sintered P/M parts behave in a similar manner, and the minimum defect size that can be detected has been determined experimentally by testing the resonant frequency after milling narrow grooves of various depths in the parts (Ref 24). It was found that defects covering 2% of the cross section could always be detected and that smaller defects (down to 0.5%) could be detected under favorable conditions of part geometry. This was later shown to apply to real defects as well as machined grooves (Ref 25). There is no record of the technique having been tried on green parts. However, the extremely high sound-damping capacity of green parts would appear to preclude its use. As with ultrasonic techniques, resonance testing has been used to determine physical properties such as the elastic modulus of materials as well as their defect structure (Ref 26).

Acoustic emissions are sounds generated in a material as stored elastic energy is released in a noncontinuous mode by mechanisms such as transformation and twinning, slip, and fracture (see the article "Acoustic Emission Inspection" in this Volume). The acoustic emission spectra have been characterized for the compressive deformation of powder-forged 4600 steels with carbon contents ranging from 0.3 to 0.9% (Ref 27).

If P/M tooling were monitored for acoustic emissions of the powder during compaction and ejection, it might be possible to distinguish emission peaks due to the release of stored energy as cracks are formed. However, a developmental program would be required to evaluate this concept and practical application is not anticipated.

Thermal Inspection

Thermal Wave Imaging. When a pulsed laser impinges on a surface, the rapidly alternating heating and cooling of the surface is conducted into the body of the specimen, as shown in Fig. 18. These thermal waves have been shown to possess many of the same characteristics as electromagnetic or mechanical waves. They can be reflected and refracted, they can form interference patterns, and they interact with irregularities contained in the transmitting medium. In coincidence with the thermal wave formation, acoustic waves are formed by the alternating expansion and contraction of the area of impingement of the laser on the surface. These photoacoustic waves have the same frequency as the thermal waves (typically 1 MHz) but have a much longer wavelength. They are also affected by scattering and reflection of the thermal waves in the volume immediately surrounding the laser impingement point, and it is this effect that allows detection of flaws. Thermal wave imaging has been used to detect delamination and microcracking in silicon integrated circuits (Ref 28).

Fig. 18 Transmission of thermal and acoustic waves in thermal wave imaging. Source: Ref 28

Another method of detecting the interactions of thermal waves with defects is optical beam deflection, or the mirage effect (Ref 29). The impingement point of the laser on the surface heats rapidly, and the air around this point is also heated. If there are no irregularities present beneath the surface, this volume of lower-density heated air is roughly hemispherical in shape. A second laser beam that transits this low-density air volume by skimming closely parallel to the specimen surface, as shown in Fig. 19, will be refracted by the density gradient in the same way as it would be by a conventional lens. A four-quadrant detector array gathers the beam deflection data as the specimen surface is scanned by the laser. Subsurface defects are detected as changes in the shape of the density gradient "lens."

Fig. 19 Detection of interactions between thermal waves and flaws by optical beam deflection (mirage effect). Source: Ref 29

Although there is no record of thermal wave imaging having been applied to P/M parts, the damping capacity of green compacts would appear to restrict the potential application of the technique to sintered components only. Full details on the principles and applications of thermal wave imaging can be found in the article "Thermal Inspection" in this Volume.

Electrical Resistivity Testing

Direct Current Resistivity Testing. A voltage field within a conductive solid will create currents that are influenced by structural irregularities, including cracks and porosity. This characteristic has been used to measure carburized case depth in wrought steels (Ref 30). The arrangement shown in Fig. 20 is used to measure the voltage drop in a current field localized between two electrode probes. This method has been used to detect seeded defects in laboratory specimens. It has also been successfully applied to the production of sintered steel parts (Ref 31), as described in Examples 1, 2, and 3.

Fig. 20 Four-point probe used in the resistivity test. The outer probe pins are the current leads; the inner pins are the potential leads. Source: Ref 30

Although the resistivity of green compacts is an order of magnitude higher than that after sintering, the same technique has been shown to apply (Ref 30). Green-state specimens with laboratory-simulated cracks of the type shown in Fig. 21 have been subjected to resistivity inspection with encouraging results. If the probe electrodes span the plane containing the defects and if a series of measurements is made along the edge of the plane, the resistivity varies when defects are present, as shown in Fig. 22. Other tests on green parts are described in Ref 30 and 31.

Fig. 21 Defects in green P/M compacts. (a) Artificial defect caused by the inclusion of a fine wax sliver in the die fill. Unetched. (b) Artificial defect produced by compacting a partially filled die at 345 MPa (25 tsi), completing the fill, and carrying out final compaction of the entire part at 620 MPa (45 tsi). Unetched. See also Fig. 22.

Fig. 22 Variation in resistivity in a green compact was used to locate artificial defects of the type shown in Fig. 21(a) and 21(b). Source: Ref 30

There are two potential contributors to variability in the resistivity test. First, in addition to cracks, the edges and corners of the parts distort the current fields. The internal corners of parts are often the sites of green cracks. Testing the volume of material immediately underlying the corners necessitates the use of specially made electrode probe sets. Another variable influencing the resistivity inspection of green compacts is the nature of the oxide layers on the particles. When the oxide layer is altered with a thermal treatment, the resistivity of the green part decreases (Ref 32).

Another study has yielded the relative density/conductivity relationship shown in Fig. 23, suggesting that resistivity tests could be used as a rapid check for localized density variations. As with ultrasound, the elastic modulus and the toughness of porous steels can also be distinguished by resistivity checks (Ref 34).

Fig. 23 Variation in resistivity with relative density in sintered iron. Source: Ref 33

The direct current resistivity test can be used on any conductive material; it is not limited to ferromagnetic materials. Although further development is needed, resistivity measurements appear to be one of the most promising techniques for the nondestructive evaluation of both green and sintered P/M parts. In addition to detecting cracks in green parts, as well as part-to-part density variation, studies have shown that changes in resistivity due to poor carbon pickup during sintering were also detectable (Ref 31). Resistivity testing has also been used later in the processing sequence to screen heat-treated parts for incomplete transformation to martensite. Several uses for resistivity testing are given in the following examples (Ref 31).

Example 1: Automotive Air Conditioner Compressor Part.

The resistivity-measuring equipment and hand-held probe are shown in Fig. 24. The part, shown in Fig. 25, was tested for green cracking in the locations marked in Fig. 25(b), which were suspect because of prior experience. The parts could then be sorted for cracks by comparing the measured resistivity with limiting resistivity values that had previously been determined using parts with cracks indicated by magnetic particle testing. The prior test method consisted of sintering, sectioning, and magnetic particle inspection, a 2-h process. This part was also the subject of a series of experiments demonstrating that the resistivity test method had high reproducibility and was not operator sensitive.

Fig. 25 Automotive air conditioner compressor part examined by resistivity measurement. (a) Actual part. (b) Cross section showing flawed areas. (c) Six location test fixture. Courtesy of R.A. Ketterer and N.F. McQuiddy, Ferraloy

Example 2: Automotive Transmission Spacer.

The resistivity test was used to screen the parts shown in Fig. 26 for incomplete transformation to martensite upon heat treating. The test is based on the lower resistivity of pearlitic microstructures compared with martensitic microstructures of the same chemistry. To determine a resistivity criterion for the screening of these parts, resistivity was correlated with hardness measurements. A resistivity of $60 \mu\Omega \cdot \text{cm}$ was associated with a hardness of 30 HRC, and a go/no-go test strategy was used. The prior test methods for this part were hardness measurements and metallography.

Fig. 26 Automatic transmission spacer examined by resistivity measurement. Courtesy of R.A. Ketterer and N.F. McQuiddy, Ferraloy

Example 3: Automatic Transmission Clutch Plate.

The part, shown in Fig. 27, was pressed, sintered, and sized. The resistivity test was then used to screen for part-to-part density variations to levels below 6.8 g/cm^3 , which was shown to be a minimum density level for achieving the radial crush strength specification for the part. Again, a limiting resistivity value was determined for the part; resistivity values below $27.5 \mu\Omega \cdot \text{cm}$ were considered acceptable.

Fig. 27 Automatic transmission clutch plate examined by resistivity measurement. Courtesy of R.A. Ketterer and N.F. McQuiddy, Ferralloy

Eddy Current Testing. Another form of resistivity testing is the eddy current test. In this test, instead of producing currents in the part by direct contact with electrodes, eddy currents are induced in the part by an alternating electromagnetic field from an induction coil, as described in the article "Eddy Current Inspection" in this Volume.

Single-Coil Tests. Disruptions in the eddy current path due to any defect that changes the resistivity of the material are detected as extraneous induced voltages in the induction coil. Alternatively, a separate detector coil can be placed in the magnetic field around the testpiece.

The alternating current in the induction coil can vary from 1 to 1000 kHz. The depth of penetration varies with frequency, with the highest frequencies yielding the smallest depths (skin effect). The way in which the eddy current varies as a function of depth is also described in the article "Eddy Current Inspection" in this Volume.

The output of eddy current testing is in the form of an oscilloscope display. An eddy current inspection system can detect changes from point to point in single testpieces (for example, welded tubes) as they move through the coil. For cases where the testpieces consist of a series of discrete parts, a second coil containing a reference can be added to the system; this configuration is called a magnetic bridge comparator.

Magnetic Bridge Comparator Testing. When a ferromagnetic part is placed in the core of a coil with an alternating current, a unique set of harmonics characteristic to the part can be detected in the coil. Some of the variables influencing the harmonics are alloy type, core or surface hardness, case depth, and porosity (Ref 35).

In the magnetic bridge comparator arrangement, the harmonic signals from two like coils are compared. The coils are similar and carry the same excitation waveform. One coil contains the part to be inspected and the other a reference part chosen at random from the group to be tested. Differences between the harmonic characteristics of the two parts are displayed as the displacement of a dot from the center of an oscilloscope screen; no displacement means the two parts are alike.

Although the magnetic susceptibility of porous sintered steels is reduced by the pinning of domain-boundary walls by pores, P/M parts are also capable of being analyzed by the magnetic bridge comparator. In one study, 120 P/M production parts were tested in a magnetic bridge comparator. Seventeen of the parts were singled out on the basis of a displacement of the oscilloscope indication, as shown in Fig. 28. These parts were tested for chemistry, hardness, crush strength, and pressed height. For comparison, 25 parts selected at random from the remaining specimens were also tested. Statistically significant differences were found between the groups with regard to carbon content and hardness (Ref 36). The technique has also been successfully applied to powder-forged parts (Ref 37). Although there are no published trials, there is a possibility that the comparator could also be used for testing green compacts.

Fig. 28 Magnetic bridge comparator display for a set of 120 sintered parts, in which 17 parts were indicated as differing from the reference part. Source: Ref 36

Visual Inspection and Pressure Testing

Magnetic Particle Inspection. Cracks that exist on or close to the surface of a ferromagnetic material in the magnetic field act as magnetic poles, creating localized increases in the field intensity. Iron particles suspended in a fluid at the surface will be preferentially attracted to these high-intensity areas, and these particles can be used to mark the locations of the flaws. The detectability of the particles themselves can in turn be improved by coating with a pigment that contrasts with the part surface or fluoresces under ultraviolet light (see the article "Magnetic Particle Inspection" in this Volume).

This method has been used to inspect finished P/M parts for cracks originating in processing, and it may also be applicable to green compacts. It is also possible to automate the inspection process by using digital image processing (Ref 38).

Liquid Dye Penetrant Inspection. A liquid that wets the surface of the material being inspected will lower its surface energy by residing preferentially in surface cracks and cavities. In the liquid penetrant inspection technique, cracks are detected by removing the dye from the flat surface of the specimen. The dye that is left behind in the cracks is then wicked out onto the surface by a fine particulate layer in which the pore radius is even lower than that of the crack. The penetrant in this particulate developer layer can be detected visually because of its high contrast with the white developer, or it can be mixed with a dye that fluoresces under ultraviolet light. This process is described in the article "Liquid Penetrant Inspection" in this Volume.

The dye penetrant equipment found in P/M shops is generally used only for checking parts of the tooling and machinery for cracks. The dye does not preferentially reside at cracks in P/M parts, because the pore radius and the crack radius are equivalent. However, there might be an application for green parts because the surfaces of green parts are sealed against penetration by liquids through smearing of the metal powder against the die wall and through the formation of a thin coating of dry powder lubricant on the surface. Cracks intersecting the surface may form an opening in this layer that could be detected by the dye penetrant.

Pore Pressure Rupture Testing of Green Compacts. A novel test is available for detecting ejection cracks in green compacts (Ref 39). A pressure seal is formed around a corner or area of a part where experience has shown that cracks are likely to occur. The area is then pressurized to about 3.5 MPa (500 psi) using a fixture such as that shown in Fig. 29. If a crack is present, the gas pressure in the crack will be sufficient to propagate the crack the rest of the way

through the part. This would be classed as a proof test rather than a nondestructive test because the part is destroyed if defects are present.

Fig. 29 Pore pressure rupture test for crack detection in green parts. Source: Ref 39

The test can be used in a nondestructive manner on sintered parts. The gas permeability of the pressurized area is measured at reduced pressures, and the presence of cracks or low-density areas is indicated by high permeability, as shown in Fig. 30.

Nondestructive Inspection of Steel Bar, Wire, and Billets

Introduction

THE INSPECTION OF STEEL BARS will be the focus of this article, but the principles involved also apply for the most part to steel wire. In many cases, as far as nondestructive inspection is concerned, steel bars and wire are the same.

Steel billets, mainly because their irregularities differ significantly from the irregularities found in bars, require special inspection techniques. Billet inspection is covered in the section "Nondestructive Inspection of Steel Billets" in this article.

The primary objective in the nondestructive inspection of steel bars and wire is generally the same as for the inspection of other products, that is, to detect conditions in the material that may be detrimental to the satisfactory end use of the product. There is, however, an additional objective in attempting to detect undesirable conditions in semifinished products such as bars, namely, to eliminate unacceptable material before spending time, money, and energy in manufacturing products that will later be rejected.

The nondestructive inspection of bars and other semifinished products does not impair the product, provides rapid feedback of information, and can be utilized as either an in-line or off-line system. It makes use of several devices, such as visual, audio, and electromagnetic, for the detection of flaws and of variations in composition, hardness, and grain structure. A wide range of selectivity is provided in each device, permitting acceptance or rejection at various specification levels. The most common function of nondestructive inspection in the steel industry is the detection and evaluation of flaws. It is also used for the detection of variations in composition and physical properties. No amount of nondestructive inspection can ensure an absolutely flawless bar, but it does provide a consistent specified degree of quality during everyday operation.

Nondestructive Inspection of Steel Bar, Wire, and Billets

Types of Flaws Encountered

The terms used for the various types of flaws discussed in this article may not be the same in various geographic areas. In many cases, different terms are applied to the same type of flaw. Therefore, this section contains a description and an illustration of each condition. The term flaw is applied to blemishes, imperfections, faults, or other conditions that may nullify acceptability of the material. The term also encompasses such terms as pipe, porosity, laminations, slivers, scabs, pits, embedded scale, cracks, seams, laps, and chevrons, as well as blisters and slag inclusions in hot-rolled products. For products that are cold drawn, die scratches may be added.

Most flaws in steel bars can be traced back to the pouring of the hot metal into molds. Factors that work against obtaining a perfect homogeneous product include:

- The fast shrinkage of steel as it cools (roughly 5% in volume)
- The gaseous products that are trapped by the solidifying metal as they try to escape from the liquid and semisolid metal
- Small crevices in the mold walls, which cause the metal to tear during the stripping operation

- Spatter during pouring, which produces globs of metal frozen on the mold walls because of the great difference in temperature of the mold surfaces and the liquid metal

Pipe is a condition that develops in the nominal top centerline of the ingot as the result of solidification of the molten metal from the top down and from the mold walls to the center of the ingot (Fig. 1). Because of the metal shrinkage and lack of available liquid metal, a cavity develops from the top down and, if not completely cropped before subsequent rolling, becomes elongated and will be found in the center of the final product, as shown in ingot B in Fig. 1.

Fig. 1 Longitudinal sections of two types of ingots showing typical pipe and porosity. When the ingots are rolled into bars, these flaws become elongated throughout the center of the bars.

Porosity is the result of trapped gaseous bubbles in the solidifying metal causing porous structures in the interior of the ingot (Fig. 1). Upon rolling, these structures are elongated and interspersed throughout the cross section of the bar product, as illustrated in Fig. 1.

Inclusions may be the products of deoxidation in the ingot, or they may occur from additives for improving machinability, such as lead or sulfur. Inclusions and their typical location in a steel bar are shown in Fig. 2(a).

Fig. 2 Ten different types of flaws that may be found in rolled bars. See text for discussion.

Laminations may occur from spatter (entrapped splashes) during the pouring of the steel into the mold. They are elongated during rolling and are usually subsurface in the bar. Figure 2(b) illustrates a lamellar structure opened up by a chipping tool.

Slivers are most often caused by a rough mold surface, overheating prior to rolling, or abrasion during rolling. Very often, slivers are found with seams. Slivers usually have raised edges, as shown in Fig. 2(c).

Scabs are caused by splashing liquid metal in the mold. The metal first freezes to the wall of the mold, then becomes attached to the ingot, and finally becomes embedded in the surface of the rolled bar (Fig. 2d). Scabs thus bear some similarity to laminations.

Pits and Blisters. Gaseous pockets in the ingot often become, during subsequent rolling, pits or blisters on the surface or slightly below the surface of bar products. Other pits may be caused by overpickling to remove scale or rust. Pits and blisters are both illustrated in Fig. 2(e).

Embedded scale may result from the rolling or drawing of bars that have become excessively scaled during prior heating operations. The pattern illustrated in Fig. 2(f) is typical.

Cracks and seams are often confused with each other. Cracks with little or no oxide present on their edges may occur when the metal cools in the mold, setting up highly stressed areas. Seams develop from these cracks during rolling as the reheated outer skin of the billet becomes heavily oxidized, transforms into scale, and flakes off the part during further rolling operations. Cracks also result from highly stressed planes in cold-drawn bars or from improper quenching during heat treatment. Cracks created from these latter two causes show no evidence of oxidized surfaces. A typical crack in a bar is shown in Fig. 2(g).

Seams result from elongated trapped-gas pockets or from cracks. The surfaces are generally heavily oxidized and decarburized. Depth varies widely, and surface areas sometimes may be welded together in spots. Seams may be continuous or intermittent, as indicated in Fig. 2(h). A micrograph of a typical seam is shown in Fig. 3.

Fig. 3 Micrograph of a seam in a cross section of a 19 mm ($\frac{3}{4}$ in.) diam medium-carbon steel bar showing oxide and decarburization in the seam. 350×

Laps are most often caused by excessive material in a given hot roll pass being squeezed out into the area of the roll collar. When turned for the following pass, the material is rolled back into the bar and appears as a lap on the surface.

Chevrons are internal flaws named for their shape (Fig. 2k). They often result from excessively severe cold drawing and are even more likely to occur during extrusion operations. The severe stresses that build up internally cause transverse subsurface cracks.

Nondestructive Inspection of Steel Bar, Wire, and Billets

Methods Used for Inspection of Steel Bars

Almost all inspection of steel bars (other than plain visual inspection) is performed by means of the following four methods, used either singly or in combination:

- Magnetic particle inspection
- Liquid penetrant inspection
- Ultrasonic inspection
- Electromagnetic inspection

Magnetic Particle Inspection

Magnetic particle inspection offers the same visual aid in the nondestructive inspection of bars as it does for castings, forgings, or machined products. The method is used for detecting seams, cracks, and other surface flaws, and, to a limited extent, subsurface flaws. As a rule, the method is not capable of detecting flaws that are more than 2.5 mm (0.1 in.) beneath the surface.

The magnetic particle method utilizes a magnetic field set up in the bar. Flaws cause a leakage of flux if they are at an angle to the flux flow. This flux is due to the lower magnetic permeability of the material in the flaw (air, oxide, or dirt) compared with that of the metal. Because the flux leakage forms magnetic poles, fine iron powder sprinkled on the surface will adhere, indicating the extent of the flaw.

Longitudinal Flaws. Optimum indications are obtained when the magnetic field is perpendicular to the flaws. A similar result is obtained for flaws slightly below the surface, but the surface leakage is less and, consequently, fewer iron particles are attracted to the area, producing a less definite indication.

Various colors of iron powders are commercially available to permit the choice of a color that provides maximum contrast between the powder and the material being inspected. Fluorescent coatings on powders and ultraviolet light can be used to make the indication more vivid. The powders can be applied in dry form, or can be suspended in oil or a distillate and flowed over the workpiece during or after the magnetizing cycle.

Transverse Flaws. To detect flaws transverse to the long axis of the bar being inspected, a solenoid winding or encircling coil is used. For longitudinal-type flaws, circumferential magnetization is utilized; an electric current flowing through the bar sets up a magnetic field at right angles to the long axis of the bar. To protect the bar from arc burns when the current is turned on, electrical contact is usually made by soft metallic pads held firmly against the bar ends.

Power Requirements. The power used can be direct current or alternating current. Direct current may be from batteries or rectified alternating current. Alternating current travels near the surface and should not be used for detecting subsurface flaws. In most cases, the continuous-magnetization system is used for bars because most bars have low retentivity for magnetism; therefore, the residual-magnetism system is not suitable. Finished bars must be demagnetized; otherwise, during manufacturing operations such as machining, steel chips will adhere and possibly cause trouble.

Quantity Requirements. As a rule, the magnetic particle inspection of bars is confined to the inspection of a small quantity of bars, as in a fabricating shop. The method is, in its present state of development, considered too slow and too costly for mass-production inspection, as in a mill. Detailed information on magnetic particle inspection as it is applied to various ferromagnetic products is available in the article "Magnetic Particle Inspection" in this Volume.

Liquid Penetrant Inspection

Liquid penetrant inspection (another visual aid), for several practical reasons, is not extensively used for detecting flaws in steel bars. These reasons include the following:

- Its use is restricted to the detection of flaws that are open to the bar surface
- Adaptation to automation is limited compared with certain other inspection methods
- Time cycles are too long for the inspection of bars on a mass-production basis

There are exceptions, however, and there are cases where liquid penetrant inspection has been used advantageously for inspecting from one to a few bars, as in a fabricating shop. Specific advantages are:

- Liquid penetrant inspection is extremely sensitive and can sometimes detect surface flaws missed by other methods
- The solvent-removable system (one of the several liquid penetrant systems) in particular is extremely flexible and can be used for inspecting bars or portions of bars in virtually any location, including in the field

Detailed information on liquid penetrant inspection is available in the article "Liquid Penetrant Inspection" in this Volume.

Ultrasonic Inspection

Ultrasonic inspection is done with high-frequency (about 1 to 25 MHz) sound waves and can successfully detect internal flaws in steel bars. Most often, the ultrasonic inspection of steel bars is restricted to large-diameter bars and to applications where high integrity is specified. Also, because of the limitations of ultrasonic inspection for detecting surface flaws, it is ordinarily used in conjunction with some other method that is more suitable for inspecting bar surfaces.

An ultrasonic beam has the valuable property that it will travel for long distances practically unaltered in a homogeneous liquid or solid, but when it reaches an interface with air (for example, at a crack or at the surface of a metal body), it is almost completely reflected. The ultrasonic beam is generated by applying a high-frequency voltage to a piezoelectric crystal, which is thus brought into mechanical oscillation. This energy in turn is fed to the workpiece by a liquid couplant.

The technique most commonly used in the nondestructive inspection of bars or barlike workpieces is the pulse-echo technique. Short pulses of ultrasonic energy are passed through the bar. The sweep voltage of the time base is coordinated with the pulse-repetition frequency so that the reflections are indicated on an oscilloscope screen. A certain amount of energy is reflected at the interface between probe and specimen, giving the first transmission signal. The probe can either have two separate crystals, a transmitter and a receiver, or have only one, which is used alternately as transmitter and receiver.

The ultrasonic method is characterized by high sensitivity and very deep penetration, but in addition to its surface limitations, its production speed is relatively low. A liquid couplant is necessary and can be a source of interference. This method is suitable for testing ingots, billets, plate, and tubes in addition to bars or barlike workpieces.

In certain cases, ultrasonic inspection has been automated. Typical products that are ultrasonically inspected using automated equipment are forged axle shafts (which are, in effect, extruded bars) and rolled bars.

Cold-Drawn Bars (Ref 1). The most effective method for the inside flaw inspection of cold-drawn bars is ultrasonic flaw detection. However, it is becoming more and more necessary to detect the smaller defects in the near-surface area in accordance with changing the production process. The conventional normal beam method (Fig. 4a) is not satisfactory, because of untested area near the surface.

Fig. 4 Schematic showing position of probe relative to flaw inside of bar and resulting wave display obtained for two methods of ultrasonic flaw detection. (a) Normal-beam method. (b) Angle-beam method. Wave display nomenclature: T, transmit pulse; S, surface reflection echo; F₁, flaw echo; B₁, back wall echo. Source: Ref 1

A testing method for detecting smaller flaws immediately under the surface of cold-drawn bars is the angle-beam method (Fig. 4b), which conveys ultrasonic waves into the material with an angle beam. It can detect the flaws immediately under the surface that are in the dead zone for the conventional normal-beam method. Entire cross-sectional area testing becomes possible with the angle-beam method and the conventional normal-beam method in combination. The testing method to feed the material spirally and to make the probes follow the deflection of the material feeding has already been adopted in practical use for as-rolled steel bars. It is difficult to obtain higher testing speed for cold-drawn bars because of smaller dimensions. Therefore, the following method has been developed in which the material is fed straight and the probes are simultaneously rotated at high speed. Table 1 lists the main specifications of the system, and Fig. 5 shows a schematic of the setup. For bars with smaller dimensions, guide sleeves and triplet rollers are used to prevent the ultrasonic incident angle to the material from changing because of excessive vibration and/or bending of the material. The water circulation system also incorporates a device that stabilizes the coupling water.

Table 1 Specifications of a rotating-type ultrasonic flaw detection system

Parameter	Specifications

Source: Ref 1

Fig. 5 Schematic of a typical rotating-type ultrasonic flaw detection system. Source: Ref 1

For flaws located immediately under the surface, the angle-beam method record can detect flaws as small as 0.2 to 0.3 mm (0.008 to 0.012 in.). Flaw echoes this small are not detectable with the normal-beam method.

Cold-Drawn Hexagonal Bars (Ref 1). Requirements for strict quality assurance are increasing for gaging inside flaws to the same level as surface flaws. The conventional testing method is manual detection with the normal-beam method. Because this method requires testing with plural directions, working efficiency is low. Furthermore, an untested zone remains at the area immediately under the surface. Therefore, a testing system using the entire cross section with higher efficiency has been sought.

Higher efficiency has been attained by incorporating an automated ultrasonic flaw detection system with probes for each face of the material to detect separately the flaws located on the inside area and the near-surface area (Fig. 6). Flaws inside the material are detected with the normal-beam method at each face of the material. In this method, the untested zone remains in the near-surface area. Therefore, surface and near-surface area flaws are detected with the angle-beam method at each face of the material. That is, six normal-beam probes and six angle-beam probes are located on the circumference of the materials to be tested, which is conveyed longitudinally. The probe positions are arranged so that the entire cross section can be detected. The probe holder is designed so that all the probes can be adjusted simultaneously by adjusting one when the material size is changed. The coupling medium is a special oil that has low ultrasonic attenuation and causes no rust on the material to be tested. Table 2 lists the specifications of the system.

Table 2 Specifications of an ultrasonic flaw detection system for cold-drawn hexagonal bars

Parameter	Specifications
Dimension of material, mm (in.)	12-32 (0.472-1.260)
Testing method	Normal-beam, 6 channels; angle-beam, 6 channels
Testing frequency, MHz	5
Probe position	Fixed in circumferential direction
Marker	Two for near-surface flaw and inside flaw

Fig. 6 Dual set of six circumferentially mounted probes used to ultrasonically detect flaws in cold-drawn hexagonal bars. (a) Normal-beam method to detect flaws deep inside bar. (b) Angle-beam method to detect surface and near-surface flaws. Source: Ref 1

Flaws larger than 0.3 mm (0.012 in.) can be detected at the near-surface area. Flaws measuring at least 0.2 mm (0.008 in.) can be detected deep inside the hexagonal bar material.

Ultrasonic Flaw Detection on Cold-Drawn Wires (Ref 1). Surface flaw inspection is important for drawn wires. A rotation-type eddy current flaw detection system is used for quality assurance. However, inside flaw inspection has been urgently needed because on-line inspection has been considered impossible.

In quality assurance for drawn wires, rotating-type eddy current flaw detection has been used in combination with rotating ultrasonic flaw detection to detect surface defects and inside flaws, respectively, in a two-step process. However, the high cost and inefficiency of this method have prompted the development of a system with a rotating-type ultrasonic flaw detection unit that can also detect surface flaws.

An additional die is placed behind the cold-drawing die to stabilize the vibration of the material. A detection unit, which has probes arrayed in a circumferential direction, is placed between these dies. There are three detection modes (Fig. 7):

- Surface wave detection mode for surface defects
- Angle-beam detection mode for near-surface defects
- Normal-beam detection mode for inside defects

Fig. 7 Principle of ultrasonic flaw detection for cold-drawn wires using three detection mode probe. Source: Ref 1

The ultrasonic incident angle can be optimized according to material dimensions. Water, the coupling medium, is always kept in full quantity even in high-speed rotation. Thus, the system has the stable mechanism to provide constant detection.

One advantage of this system is that linear defects can be detected by surface wave detection at the same level as an eddy current method. Another is that the entire cross section can be covered by means of a combination angle-beam/normal-beam method. Table 3 summarizes the specifications of this setup.

Table 3 Specifications of an ultrasonic flaw detection system for cold-drawn wires

Parameter	Specifications
Dimension of material, mm (in.)	15-30 (0.590-1.181)

Signal transmit	Noncontact rotation transmit
Marker	One each for near-surface flaw and inside flaw

Source: Ref 1

Results of experiments with this system showed detectability of 0.1 mm (0.004 in.) minimum flaw depth on surface defects and 0.2 mm (0.008 in.) minimum inside defect size. This system enables the user to inspect the entire cross section of cold-drawn wires to a high degree of accuracy. Detailed information on the fundamentals, equipment, and techniques for ultrasonic inspection is available in the article "Ultrasonic Inspection" in this Volume.

Electromagnetic Inspection Methods

Electromagnetic methods of inspection are used far more extensively for nondestructive inspection of steel bars than any of the methods discussed above. Electromagnetic methods are readily adaptable to automation and can be set up to detect flaws, as well as a number of different compositional and structural variations, in bars on a mass-production basis.

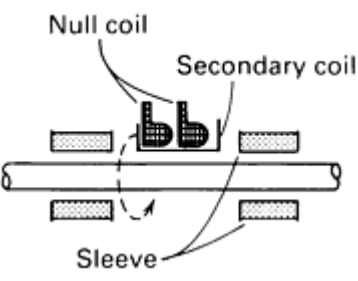

Equipment can be relatively simple, but for mass-production inspection the equipment may be highly sophisticated and costly. Such equipment can not only detect flaws and indicate them on an oscilloscope or other form of readout but can also mark the location of the flaw on the bar before it emerges from the inspection equipment and can automatically sort the bars on the basis of seam depth.

Eddy Current Testing of Cold-Drawn Bars (Ref 1). Surface defects on cold-drawn bars can be inspected by eddy current detection methods using an encircling coil. This method utilizes a rotating probe that detects surface defects with the probe coil rotating at high speed around the circumference of the cold-drawn bars.

The encircling coil method exhibits lower detectability on linear flaws because flaw detection depends on the difference between two test coils in which the material to be tested is encircled. On the other hand, the method of rotating the probe coil at high speed along the circumference of the material to be tested can detect linear defects because it detects bars in spiral scanning.

Table 4 lists the specifications of the detection system. One of the main features is signal transmission in the probe rotation unit by the noncontact rotating transmit method, which requires no maintenance work. Guide sleeves are placed in front of and behind the probe to maintain a constant distance between the probe and the material to be tested, which is important for acceptable performance of the system (Fig. 8). Furthermore, the rotation axis of the probe and the axis of the material to be tested are kept in a line by pinch rollers placed in front of and behind the detector. On the probe, a distance sensor is used for the automatic gain control function to provide electric compensation against distance variation.

Table 4 Specifications of a rotating probe type eddy current flaw detection system

Fig. 8 Schematic of a rotating probe type eddy current flaw detector. Source: Ref 1

Figure 9 shows the relation between flaw depth and signal output. Natural flaws produce a larger deviation in signal output than artificially introduced flaws because of the complicated cross-sectional configuration of the flaw, but the

minimum detectable flaw depth is 0.1 mm (0.004 in.). Detectable flaw length depends on the feeding speed of the material, the number of probes, and the number of rotations. For example, at a speed of 60 m/min (200 sfm), the full surface is converted, and the minimum detectable flaw length is as long as the length of the probe coil.

Fig. 9 Plot of eddy current signal output versus flaw depth to gage detectability of flaws in cold-drawn bars. Source: Ref 1

Eddy Current Flaw Detection on Cold-Drawn Hexagonal Bars (Ref 1). Cold-finished steel profiles (hexagonal bars) are mainly used as the raw material for couplers in oil pressure piping, an application for which quality assurance is important. Surface defects on cold-drawn hexagonal bars include cracks derived from the cold-working process as well as material flaws, both of which are long, longitudinal defects. It is impossible to detect these defects by the differential method using encircling coils. The rotating probe method is also not applicable, because of the hexagonal form. An automated flaw detection system for cracks initiated by the working process was developed using the eddy current flaw detection system by a standard voltage comparison method.

There are two methods for testing cold-finished steel hexagonal bars: the standard voltage comparison method with encircling probes (Fig. 10b) and the differential method with probe assembly (Fig. 10c). There is no effective difference in detectability between these two methods. For the probe assembly method, it is necessary to consider the differences in detectability of each individual probe, which is not necessary for the standard voltage comparison method.

Fig. 10 Eddy current flaw detection method for cold-drawn hexagonal bars. (a) Location of artificial flaws ranging from 0.5 to 19 mm (0.020 to $\frac{3}{4}$ in.) below probe position. (b) Schematic of setup for standard voltage comparison (encircling coil) method (left) and plot of signals obtained for the designated flaw depths (right). (c) Schematic of setup for differential (six probe coil assembly) method (left) and plot of signals obtained for the designated flaw depths (right). Source: Ref 1

The standard voltage comparison method is inferior in detectability to the rotating probe method, but is less expensive and can efficiently detect cracks resulting from the cold-working process. This method, which can detect material flaws more than 0.6 mm (0.024 in.) deep, is illustrated in Fig. 11.

Fig. 11 Plot of eddy current signal output versus flaw depth to measure detectability of flaws--specifically material flaws (open circles) and process-induced cracks (closed circles)--in cold-drawn hexagonal bars. Source: Ref 1

Eddy Current Flaw Detection of Cold-Drawn Wires (Ref 1). Surface flaw detection on wire drawing line has been conducted by the encircling-type eddy current method. However, this method has difficulty in detecting linear flaws. A rotating probe type eddy current detection method can be effective, as illustrated in Fig. 8 for use on cold-drawn bars. It is important in the rotating probe method to maintain a constant distance between the probe and the material to be tested. The rotating unit, is positioned between dies where the smaller vibration of the material is expected. Guide sleeves are used to adjust the rotating axis and the axis of the material to be tested.

Detectability is illustrated in Fig. 12. Flaws having a 0.1 mm (0.004 in.) minimum depth are detectable.

Fig. 12 Plot of eddy current signal output versus flaw depth to measure detectability of flaws, specifically cracks (open circles) and scabs (closed circles), in cold-drawn wires. Source: Ref 1

Eddy Current Flaw Detection for a Cold-Forged, High-Tensile Sheared Bolt (Ref 1). Figure 13 shows a general view of a high-tension sheared bolt. This type of bolt has a head with a round cross section and is mainly used for general construction and bridge applications. This bolt is produced by cold forging from cold-drawn wires in the diameter similar to the outside diameter of a threaded part of the bolt. The head is the most severely processed part of the bolt. The circumferential part of the bolt head is formed between punch and die during cold forging. Therefore, cracks tend to occur on the head. Eddy current testing can detect flaws in the bolt head at high speed with the probe rotating method.

Fig. 13 Schematic of a high-tension sheared bolt.

Figure 14 shows a general view of the inspection system used. Table 5 lists the main specifications. Bolts are conveyed from hopper to line-up unit. Lined-up bolts are conveyed to the index table by straight feeder and then conveyed intermittently to the rotating detection head and further to the separator.

Table 5 Specifications of an eddy current detection system for a high-tension sheared bolt

Parameter	Specification
Material	M20

Testing speed, pieces/min	60
Number of rotations of detecting head, rev/min	300
Testing frequency, kHz	125
Probe type	Self induction, self comparison

Source: Ref 1

Fig. 14 Schematic of eddy current flaw detection system used to inspect sheared bolt illustrated in Fig. 13.
Source: Ref 1

After the bolt heads are detected with the rotating detection head, the bolts are classified as good/no-good and separated according to detection result. Figure 15 shows the operation of the rotating detection head. The rotating detection head repeats the following operations while rotating continuously regardless of the position of the bolt head to be tested:

- A bolt stops immediately under the detection head (Fig. 15a)
- The detection head descends while maintaining rotation (Fig. 15b)
- The detection head approaches the bolt head, scans around the bolt head for two revolutions, and detects the flaws (Fig. 15c)
- Pincerlike probe holders release from the bolt head, and the detection head ascends
- Bolt is conveyed to separator while next bolt is conveyed to the position immediately under detection

head

Fig. 15 Operation of rotating eddy current detection head. (a) Shear bolt positioned under rotating detection head. (b) Rotating detection head descends to lower probes into position to inspect bolt head. (c) Probe scans bolt head as bolt undergoes two complete revolutions to detect flaws. Source: Ref 1

A detection rate of 60 pieces/min was maintained by the mechanism to keep the detection head rotating continuously. Figure 16 shows the relation between flaw depth and signal output. Noise level is high at the circumferential surface of the bolt head because of surface roughness, but the minimum detectable flaw depth is 0.3 mm (0.012 in.). Detailed information on methods of electromagnetic inspection is available in the articles "Eddy Current Inspection" and "Remote-Field Eddy Current Inspection" in this Volume.

Nondestructive Inspection of Steel Bar, Wire, and Billets

Electromagnetic Systems

Electromagnetic systems include the systems that use magnetic fields generated by alternating current flowing in a solenoid. A wide range of frequencies is used. As the alternating current flows through the solenoid, the magnetic field generated induces eddy currents within the metal workpiece. These currents are affected by the electrical resistivity (more commonly expressed as electrical conductivity--the reciprocal of resistivity), magnetic permeability, configuration, homogeneity, surface irregularities, and flaws of the metal. The resistivity of the workpiece can vary because of the chemical composition, crystal orientation, structure, and history of mechanical working. Permeability will vary over a broad range, depending on the amount of stress present in the work metal. It increases slightly in the vicinity of a flaw when the bar is subjected to a stress-producing operation.

Electromagnetic systems of flaw detection are broadly classified as:

- Those depending primarily on variations in electrical conductivity
- Those depending primarily on variations in magnetic permeability

Both systems are capable of detecting flaws in ferromagnetic bars. The conductivity-dependent systems can also be used to detect flaws in nonferromagnetic bars.

Nondestructive Inspection of Steel Bar, Wire, and Billets

Eddy Current Systems

When electrical conductivity (resistivity) is the major variable relied upon, the test procedure is known as the eddy current system. The alternating-field intensity is low, permitting the use of a correspondingly small inductor. Most eddy current systems use a constant-voltage input derived from an electronic oscillator with a means of varying the output frequency through a wide range, such as from 0.5 to 1000 kHz, in discrete steps.

For general flaw detection, the range of 1 to 50 kHz is widely used. For ferromagnetic bars, a means must be provided to eliminate or minimize the effects of permeability variation. This is usually accomplished by magnetically saturating the bar being tested. The means for doing this is either a dc solenoid or a strong permanent magnet. A longitudinal section of one type of eddy current coil assembly is shown in Fig. 17, a more detailed drawing of the rotating coil setup shown in Table 4.

Fig. 17 Coil assembly for the inspection of steel bars by the eddy current system. Dimension given in inches

Eddy current inspection is especially useful for detecting and evaluating seams in steel bars. With this system, depending on the circuitry used, a difference of as little as 0.025 mm (0.001 in.) in seam depth can be detected. Because of the skin effect, the ability of eddy currents to penetrate into the test metal decreases in proportion to the increase of the frequency.

Eddy current inspection can be used without magnetic saturation for inspecting hot bars in the mill when the metal is above the Curie temperature, because the metal is nonmagnetic at this temperature. Therefore, it follows that the magnetic permeability system cannot be used to inspect hot bars.

Nondestructive Inspection of Steel Bar, Wire, and Billets

Magnetic Permeability Systems

Systems that depend on variations in magnetic permeability can be used for detecting flaws and for detecting differences in composition, hardness, or structure. With appropriate instrumentation, both functions can be accomplished simultaneously.

Flaw Detection. Magnetic permeability systems usually employ a solenoid (primary coil), which is excited by the standard line frequency of 60 Hz with an adjustable current control to produce magnetic fields from 1000 to 30,000 ampere-turns; however, the solenoid is usually operated in the range of 10,000 to 15,000 ampere-turns. A typical coil arrangement used for permeability systems is shown in Fig. 18.

Fig. 18 Coil assembly used for the simultaneous detection of flaws and of variation in composition, structure, and hardness in steel bars. Dimension given in inches

As seen in Fig. 18, the coil arrangement consists of a primary coil (60 Hz), two null coils (zero-voltage-output coils), and two standard coils. The secondary or pickup coils (null coils) are concentric with the primary coil, connected electrically in opposition, and adjusted to a null or zero-voltage output. The null coils are usually spaced 75 to 102 mm (3 to 4 in.) apart. The reason for this spacing is that a normal seam in a bar tapers into the bar to sound material. The variation in stress level producing a measurable change in magnetic permeability is related to the change in seam depth found usually within 75 mm (3 in.) of seam length.

Limitations for Flaw Detection. The detection of flaws by permeability systems depends on permeability variations resulting from changes in stress, due to cold work or heat treatment, in the adjacent area of the flaw. These changes are more or less directly proportional to the change in stress up to the elastic limit of the ferrous product.

These systems cannot be used to inspect hot-rolled or annealed bars unless they have been subjected to some uniform cold work, such as rotary straightening for round material or planar-type straightening for square, hexagonal, or flat sections. Gag-straightened bars are not suited to inspection by permeability systems, because of nonuniform high-stress concentrations wherever the ram meets the work metal. Such stresses are far in excess of those for flaws in uniformly stressed material.

The efficiency of flaw detection is a function of uniform residual stress levels within the bar. The five conditions that follow are listed in order of decreasing efficiency for detection of flaws by permeability systems:

- Heat treated, quenched, drawn, and machine straightened
- Cold drawn and machine straightened
- Cold drawn, annealed, and machine straightened
- Hot rolled and machine straightened, centerless ground

- Hot rolled and machine straightened

After straightening, the bars should be aged 24 to 48 h at near room temperature for optimum sensitivity of flaw detection. Aging can be hastened by stress relieving at low temperature in a furnace (up to 260 °C, or 500 °F).

The minimum seam depth that can be detected in cold-drawn, straightened round bars is approximately 0.025 mm (0.001 in.) for each 1.6 mm ($\frac{1}{16}$ in.) of bar diameter; hexagonal and square bars with the same processing will be more sensitive. For example, in a 25 mm (1 in.) diam round bar, a 0.41 mm (0.016 in.) seam is readily detected, while a 0.30 to 0.33 mm (0.012 to 0.013 in.) seam can be detected in hexagonal or square bars. The reason for this difference lies in the residual stress levels imparted by the rotary and planar straighteners.

Other flaws, such as laps, slivers, cracks, hard or soft spots, dimensional changes, cupping, chevrons, and pipe, are readily indicated. For subsurface-type flaws, detection is possible only if they lie within the normal penetration range and are of sufficient size to affect the inherent stress level. The penetration is approximately 6.4 mm ($\frac{1}{4}$ in.) for low-carbon steels, 7.9 mm ($\frac{5}{16}$ in.) for medium-carbon steels, and up to 13 mm ($\frac{1}{2}$ in.) for many alloy steels.

One other factor not to be overlooked is the end effect, which prevents end-to-end inspection of the bar. As the front and rear ends of the bar enter and leave the magnetic field, the field is grossly distorted, preventing inspection of the end portions of the bar. For the average inspection speed of 37 to 46 m/min (120 to 150 sfm), the noninspected lengths will be as follows:

Bar diameter		Noninspected length at each end	
mm	in.	mm	in.
6.4-13	$\frac{1}{4}$ - $\frac{1}{2}$	102-152	4-6
13-25	$\frac{1}{2}$ - 1	152-203	6-8
25-50	1-2	203-305	8-12
50-75	2-3	305-406	12-16

The signal obtained for a flaw of given size, as well as the amount of end effect, will vary somewhat with the amount of draft used in drawing the bar. Using the normal 0.8 mm ($\frac{1}{32}$ in.) draft as the basis for comparison, a 1.6 mm ($\frac{1}{16}$ in.) draft will increase the signal size by 50%, while a 3.2 mm ($\frac{1}{8}$ in.) draft will produce an increase of about 90% (Fig. 19).

Fig. 19 Relationship between increase of flaw signal and increasing reduction of cross section (increasing draft) for cold-drawn steel bars. Base reference is a hot-rolled bar.

All the above values hold true only when the secondary test coil is of the proper size; that is, the inside diameter of the coil should be 3.2 to 6.4 mm ($\frac{1}{8}$ to $\frac{1}{4}$ in.) greater than the bar diameter. The diameters of bar stock inspected by these systems generally range from 4.8 to 140 mm ($\frac{3}{16}$ to $5\frac{1}{2}$ in.).

Equipment for Detecting Flaws. The circuitry may include three types of electronic systems: the null system for the detection of flaws (as explained above and shown in Fig. 18) and two identical standard systems, one of which is used for detecting mixed grades in a given lot of steel and the other for indicating variations of hardness or structure. All systems are independent and provide simultaneous indications with a single pass of the bar through the coil.

The null system utilizes a pair of matched windings that provides for the comparison of a section of the bar with another section spaced some distance from the first. The matched windings are connected in opposition, and the resultant voltage is therefore theoretically zero, making the wave displayed on the oscilloscope a straight line. In practice, however, such a balance is seldom obtained. A small voltage with the wave-shape showing two peaks phase displaced 180° can normally be seen on the oscilloscope screen (bar out, Fig. 20). When a bar is placed within the coils, the wave pattern changes (bar in, Fig. 20). Should a flaw of minimum depth be present, the change in the waveshape is too small for measurement, even though there is a differential voltage between the null coils. Therefore, other relationships must be used to provide the desired information.

Fig. 20 Waveshape for oscilloscope pattern of a full electrical cycle for empty coils (bar out) and loaded coils (bar in). The position of an electronic gate for viewing an established portion of the cycle is shown.

The use of an electronic gate of any desired width permits these measurements to be made in any section of the wave. For example, the test gate shown in Fig. 20 is adjustable to any position of the 360° cycle. It is normally positioned 8 to 20° on either side of the stress peaks, where experience has revealed the wild stress effects are minimal and waveform changes for flaws are readily detectable. Most systems provide a second electronic gate that can monitor the section of waveshape where flaws cause a change in the saturation level, if this can be reached for the size and grade of material under test. Deflections greater than a predetermined amount will energize a signal that indicates rejection.

Use for Sorting. The two standard systems differ from the null in that only one coil winding for each is utilized on the bar being tested (Fig. 18). The voltage derived from this coil is balanced by a voltage in the instrument that is fully adjustable to the degree that the zero-center meters can be adjusted to their midpoint while the oscilloscope presentation continually shows the distorted waveshape. Should any undesired bars appear within the lot being tested, the meter deflection will then provide power for activation of suitable alarm devices. The selectivity of the section of waveshape to

be monitored is provided by an electronic gate, adjustable through 180° . Only half of the full 360° wave is required, the remainder being the negative duplicate of the positive and not shown on the oscilloscope. Both systems (standard coils, Fig. 18) are fully independent and should be operated at different positions of the waveform to obtain as much information as possible during the test. The standard system is used to monitor each bar in a lot for composition, hardness, structure, and size and to indicate the presence of uniform-depth seams, cracks, and laps, which generally escape detection by the null system.

Nondestructive Inspection of Steel Bar, Wire, and Billets

Equipment Requirements

In addition to coil arrangements such as those illustrated in Fig. 17 and 18, a fairly elaborate set of electronic gear is required for inspecting steel bars. Some type of equipment for handling the bars and conveying them through the coils at the desired rate is also required. The degree of sophistication designed into the equipment depends mainly on the number of similar bars to be inspected.

Typical control units are adaptable to either the eddy current or the magnetic permeability systems of inspection. Many variations are commercially available.

Nondestructive Inspection of Steel Bar, Wire, and Billets

Flaw Detection Procedure Using a Permeability System

The following description is presented purely as an example of setting up a procedure for detecting flaws by permeability change using the null coils with one specific type of instrumentation. Procedures vary widely for various types of equipment.

Select the proper size of secondary coil for the bars to be tested, and insert it into the primary-coil unit, making sure all electrical connections are secure. Turn on the primary power, and adjust the coil current to about 8 A as shown on the electrical meter on the power-supply panel. Adjust the combined coil unit so that the material will be concentric with the inside diameter of the secondary coil. Select the appropriate feed-through speed of the conveyor system, and insert a bar into the test coil. Turn the sensitivity on the null-equipment panel clockwise to about midposition, and while the bar is moving in the forward direction, alternately adjust the balance x and y controls to bring the null waveshape, as seen on the oscilloscope, to as near a straight line as possible. Do not stop the bar while making these adjustments, because it heats rapidly and its permeability changes with increasing temperature, resulting in a flaw indication when passed through the test coil on a repeat run. Furthermore, do not adjust the controls when the feed is reversed through the test coil, because the magnetic field is dragged by the bar in the direction of travel and the balance obtained would not be correct for the normal feed direction.

Assuming the oscilloscope controls are adjusted properly, the two stress peaks of the null waveshape will be located equidistant from the edge of the tube face and 180° apart. Locate the index or gate about 10 to 15° to the right of the left stress peak by use of its control knob, and adjust its height by the gain control so that it is easily recognizable. The choice of using a 60-Hz filter, either in or out, is based on past experience when testing the same type of material with a similar setup. Finally, readjust the sensitivity control so that the small fluctuations within the gate do not reach the preset trip level for the various signaling devices.

Nondestructive Inspection of Steel Bar, Wire, and Billets

Sorting Procedure Using a Permeability System

The following example of a procedure for sorting involves the use of the standard coils (Fig. 18) for detecting variations in hardness, grade, and structure, employing three different electronic gates within 180° (one-half cycle). In this case, the same package of electronic gear is used for pickup from both the null and the standard coils.

Position the waveshape switch to the respective A or B standard circuit, and its oscilloscope trace will appear on the face of the tube in place of the former null trace. Adjust the sensitivity control to the third or fourth step, and with a bar feeding through the test coil, position the gate to its desired location by means of the coarse-gate and fine-gate set controls. The associated zero-center meter will deflect either to the positive or negative side, and by turning the compensator knob in the appropriate direction to deflect it toward its midpoint, the meter can be balanced to zero. A rough adjustment can be made with the bar stationary in the test coil. When the bar is heated, the oscilloscope pattern continually changes. By moving the bar forward two or three times while making the above adjustments, the final balance can be obtained. The same procedure is used for the other circuit, but the gate should not be at the same position on the electrical cycle (Fig. 21). Figure 21 shows the waveshape for one-half of an electrical cycle for a bar of 1141 steel. The three gate positions for detecting variations in hardness, grade, and structure are indicated on the waveshape.

Fig. 21 Waveshape for one-half of an electrical cycle as seen on the screen of an oscilloscope with a bar of 1141 steel in the coil. Three electronic gate positions are indicated for inspecting for hardness, grade, and structure.

The bar that was used for setup purposes should be set aside until testing of the whole lot of material is completed, because every bar is being compared to the setup bar. Should the meters exhibit a deviation for the whole length of the bar, the bar could be a different grade or contain a full-length seam or crack. A varying meter reading may indicate a change of hardness or structure as well as a deep flaw. The latter will be simultaneously indicated by the null circuit. If an unwanted grade of steel bars has been separated, it is advisable to retest this group, choosing one bar from the unwanted lot for setup, because it is not unusual to find a third grade within a mixed lot of steel.

Nondestructive Inspection of Steel Bar, Wire, and Billets

Nondestructive Inspection of Steel Billets

Steel billets are generally less uniform in section and straightness than steel bars. Furthermore, billet surfaces are usually less refined and therefore not as smooth as bar surfaces. These characteristics of billets make it more difficult to establish methods and procedures for nondestructive inspection. The methods described in this section are applicable to the common rolled round-cornered-square billets.

Surface Preparation

Regardless of the method used for billets, inspection results are greatly improved when they are free from excessive scale and blisters. Tightly adherent scale usually does not interfere with inspection unless it is thick enough to affect the sensitivity of the inspection method. Two common methods for preparing the billet surfaces for inspection are pickling in hot acid and gritblasting.

Magnetic Particle Inspection

The visual inspection of billets has been upgraded by the addition of the magnetic particle method. The principles involved in the magnetic particle inspection of billets are essentially the same as those for the magnetic particle inspection of other ferrous products or product forms (see the article "Magnetic Particle Inspection" in this Volume). As a rule, the wet fluorescent particle system is chosen for inspecting billets.

Magnetic particle inspection has improved the ability to detect obscure flaws, and through the use of mechanical handling equipment, inspection can be accomplished quite rapidly. However, this method is subject to some of the inherent disadvantages of visual inspection. Test results depend on the alertness and eyesight of the operator and on his ability to judge the severity of the flaw. Other variables, such as magnetizing current, particle size, and contamination of the particle bath by foreign substances, can vary the intensity of the flaw indication and thus increase the difficulty of appraising its severity (Fig. 22). Another factor is that, even when the above conditions are controlled, the magnetic leakage field attracting the particles is not uniform across the flat face of a square billet. The field density is maximum at the center of the flat face and almost nonexistent at the corners of magnetized billets. Consequently, the particle concentration and the flaw indication decrease with distance from the center for any one of the four flat faces.

Fig. 22 Seam indication width versus magnetization current for a 105×105 mm ($4\frac{1}{8} \times 4\frac{1}{8}$ in.) 1021-1026 grade steel billet. Seams tested: center of billet face perpendicular to billet surface; seam or portion of seam with width ≥ 0.025 mm (0.001 in.) for a total depth of 0.76 mm (0.030 in.). Magnetic particle sizes: type I, 3 to 28 μ m (120 μ in. to 0.0011 in.) (major % = 8 to 18 μ m, or 320 to 720 μ in.); type II, 15 to 60 μ m (600 μ in. to 0.0024 in.) (major % = 28 to 48 μ m, or 0.0011 to 0.0019 in.); special type II, 40 to 74 μ m (0.0016 to 0.0030 in.) (major % = 44 to 62 μ m, or 0.0017 to 0.0025 in.). Bath application: 76 L (20 gal.) pressurized mixing tank with hose and hand-operated applicator. Source: Ref 2

Another magnetic test for the inspection of billets also requires the billet to be magnetized. Instead of using particles, a magnetic tape placed close to the billet surface is used to detect the presence of flaws. The flux leakage resulting from a surface discontinuity is recorded on the tape. The tape is then scanned by a tiny probe coil, which detects the flux leakage recorded on the belt. The probe transforms the magnetic leakage into an electrical signal. The signal transmitted to the control cabinet by means of contactless transformers will, if it is larger than a preset value, operate an alarm or marker.

The billet face is usually divided into five to ten tracks, each about 19 mm ($\frac{3}{4}$ in.) wide. The signal operates an electronic trigger circuit, which trips the appropriate indicator for the track in which the flaw lies.

This method eliminates a deficiency of the magnetic particle test in that the interpretation of results is not dependent on an operator. Also, the use of compensating circuitry reduces the differential in sensitivity to flaws from the middle to the corner of the billet.

Rolled Versus Continuous-Cast Billets (Ref 2). The major flaw types for rolled-steel billets are surface or near-surface seams, which are primarily oriented along the length of the billet. For continuous-cast products, in the as-cast state, flaws include surface cracks oriented in the transverse direction and round near-surface flaws such as slag pockets.

There are two basic methods of magnetic field application. For detecting longitudinal seams or cracks, the circular magnetization method is used. For detecting transverse seams or cracks, longitudinal (or coil) magnetization is used. For continuous-cast billets, circular and coil magnetization have been applied simultaneously. To detect multidirectional near-surface flaws and surface flaws, it is convenient to use simultaneously a dc field for circular magnetization and an ac field for longitudinal magnetization.

Generally, the billets are 3 to 14 m (10 to 45 ft) in length. The large billets are often referred to as blooms. To apply the circular field, the current is passed directly through the billet longitudinally. To apply the longitudinal field, the billet is placed along the axis of the coil, and either the billet or the coil is moved relative to the other.

In the wet magnetic particle method, for economy and handling convenience, a common carrier of the particles is water. The particles are formulated so that they will not easily deteriorate in prolonged mixture with water. Other ingredients can be added to facilitate the use of such a mixture, such as a wetting agent to disperse the particles and properly wet the part surface, antifoaming chemicals to reduce the suds due to agitation, and antifreeze to keep the bath from freezing in winter. If needed, fixer or binder can also be added to the bath to make the dried indications durable enough to withstand the normal handling in the mill.

Inspection of Rolled Billets. Typically, particle types with sizes ranging from less than 10 to 70 μm (400 $\mu\text{in.}$ to 0.003 in.) are often adequate to find the significant seams in rolled-billet inspection. The finest-size particle, 6 μm (240 $\mu\text{in.}$) or less, is good for finding extremely minute flaws—for example, inclusion flaws as small as 25 μm (0.001 in.) wide in 0.25 mm (0.010 in.) thick steel sheets. For these flaws, larger-size particles may be ineffective; significant leakage fields are confined to very small areas. The total forces exerted on the individual particles are usually weak a short distance away, and the relatively bulky size and the momentum of large particles would prevent most of them from getting close enough to the flaws to be strongly attracted and stay there. As a result, either too few magnetic particles are retained at the flaw sites to contrast with the background, or the indications can be easily disturbed by their own weight and by the bath flow.

However, very fine and shallow flaws are not important in practical billet inspection, in which flaw depths greater than 0.64 mm (0.025 in.) are often the only ones of interest. (When reheated, the outer skin of the billet with shallow flaws will be oxidized to become scale and will fall off the part during further rolling operations.) Therefore, particles with nominal diameters of 10 to 50 μm (400 $\mu\text{in.}$ to 0.002 in.) are often used to give large indications for the significant seams and to ignore very minor ones.

The ultimate choice of particle type is not determined by particle size alone. Other factors, such as the magnetic properties, color, and brightness of the particles, must also be considered.

For the proper magnetization current level, a rule of thumb has been developed: Roughly 1000 Adc per 25 mm (1.0 in.) of material diameter is satisfactory for most critical inspections. The equivalent surface field is about $1.2 \times 10^4 \text{ A} \cdot \text{m}^{-1}$ (157 Oe). For most practical large-billet inspections, less than half this value is used.

Inspection of Continuous-Cast Products. Slag pockets, transverse cracks, and longitudinal cracks are the typical flaws found in continuous as-cast products (billets, blooms, and slabs). The slag pockets are near-surface inclusions. In a few cases, they can be partially exposed to the surface. The inclusions are mainly slags. There may also be voids with coats of oxidelike chemicals on the walls. They are often approximately round, but can be elongated in depth or longitudinal direction. Depending on product type, the largest slag pockets uncovered in the laboratory can be 3.2 to 6.4 mm ($\frac{1}{8}$ to $\frac{1}{4}$ in.) in diameter. The smallest ones may have diameters less than 0.8 mm ($\frac{1}{32}$ in.). The pockets are generally found within a 2.5 mm (0.1 in.) deep layer under the product surface. Small slag pockets are often found near the surface. Cracks in the continuous-cast products have been observed to be deep and tight, with inclusions. The cracks can occur in the direction of the oscillating mold marks (transverse corner cracks) or perpendicular to that direction. Depending on the casting technique, they can occur in groups and branch out in all directions like a web, covering significant areas.

In general, the discussions about seam indication formation in rolled billets can be applied to crack indications in the continuous-cast product. For example, in the case of slag-pocket indications, the parameter equivalent to the seam width is the indication diameter. However, there are still a few differences between rolled-billet inspection and continuous-cast bloom inspection.

Differences in Magnetization Levels. The magnetization level used in continuous-cast product inspection is usually stronger than that required for rolled billets. Because of the subsurface nature of the flaws and the wider flaw dimensions,

the attraction of the magnetic particles to the leakage fields for the flaws is not as intense as the attraction normally found in rolled billets. Therefore, the magnetization levels often must be higher.

The magnetization technique for the continuous-cast product is more complicated because magnetization is needed in both circular and longitudinal directions. When simultaneously applied multidirectional magnetization is used, the combined field effect equals the oscillating field (swinging vector) on the part surface.

Eddy Current Inspection

One advantage of the eddy current inspection of billets over magnetic particle inspection is that uniform results can be obtained without significant involvement of operator judgment. Another advantage is that the corners of a billet can be eddy current inspected to the same degree of thoroughness as the flat surfaces.

There are, however, certain problems involved in the eddy current inspection of billets. Billets are not sufficiently uniform in cross section or straightness to permit their being fed through encircling coils. Also, this type of coil is not very sensitive in detecting the longitudinal-seam type of flaw. Therefore, the eddy current inspection of billets is usually performed by using probe coils. Figure 23(a) illustrates how a probe coil induces eddy currents in the billets, and Fig. 23(b) illustrates how the flow of eddy currents is changed by the presence of a seam in a billet.

Fig. 23 Schematics of eddy current flow. (a) Eddy current flow around a probe coil for a sound billet. (b) Eddy currents flowing around the seam in a defective billet, thus altering the electrical loading on the probe coil

It is not feasible, however, because of the inherent cross-sectional shape of square billets, to inspect by merely rotating them around the surface. The probe would bounce and this would excessively vary the distance between the billet surface and the probe coil, thus degrading the accuracy of the results. Also, the rapid bounce could generate false signals. Therefore, another approach must be taken.

Use of Rotary Probe Unit. One approach is the use of a rotary probe unit such as that illustrated in Fig. 24. The significant components of this unit are search probes mounted in a housing to which is attached a tungsten carbide wear shoe and an arrangement of hardened steel rollers. This entire assembly is spring actuated. This unit and usually a second one like it are mounted 180° apart on a drum-shaped assembly. Two probes are mounted in each unit to increase the amount of inspection coverage. Electrical energy reaches the search probes through slip rings. The units rotate around the billet as it progresses through the drum assembly. As can be seen in Fig. 24, the coil in the search probe is, at all times, the same distance from the billet surface, separated only by the tungsten carbide wear shoe. The spring-actuated rollers move as required to aid in holding the search probe on the billet surface as the entire unit revolves around the billet.

Fig. 24 Rotary probe unit used for the eddy current inspection of steel billets, and graph showing effect of position on speed as the probe unit traverses radially over one quadrant of a 102 mm (4 in.) square billet

One requirement for accurate results is that the speed of the probe relative to the test surface must be maintained within certain limits. Experimental studies have established that the optimum range for this eddy current test is 25 to 43 m/min (80 to 140 sfm). A probe speed below this range results in an inconsistent measurement of flaw depths. Speeds above this range cause objectionable electronic noise.

The graph in Fig. 24 shows the relative speed of the probe at different positions on one quadrant of a 102 mm (4 in.) billet section. Many of the dimensions of the probe assembly components affect the instantaneous velocity of the probe relative to the billet surface. Therefore, the dimensions of the elements must be selected so as to impart to the probe a velocity that is maximum on the flat, where bounce is least likely to occur, and minimum near and around the corner, where the coil has the greatest tendency to leave the surface. The speed fluctuates smoothly within the allowable testing range as the probe assembly is rotated around the billet.

The rotary probe unit shown in Fig. 24 can be used to test billets ranging from 75 to 152 mm (3 to 6 in.) square. For other sizes, the dimensions of the components of the unit must be changed accordingly.

The forward speed of the billet conveyor is between 7.6 and 23 m/min (25 and 75 sfm). The forward speed that can be used depends on the size of the billet and the length of the flaws that must be detected. The inspection is performed on a spiral band on the surface of the billet; the pitch of the spiral (and therefore production rate) is determined by the minimum length of flaw to be detected. Production use in one mill calls for the detection of all flaws 25 mm (1 in.) and longer, resulting in a speed of 12 m/min (40 sfm) for 102 mm (4 in.) billets and 10 m/min (34 sfm) for 127 mm (5 in.) billets. At these speeds and with no delays, 41 to 54 Mg/h (45 to 60 ton/h) can be inspected in one machine.

Marking the flaws is done with spray markers that are mounted near and rotate with the search-probe assemblies. One marker is used per search-probe assembly, and either of the two search probes will activate the marker. With this arrangement, the marks always lead, by a short distance, the actual longitudinal location where the flaw was detected. The circumferential position of the flaw is marked exactly, because the spray markers are displaced from the probe centerline at a distance that is equal to the distance that the faceplate rotates during the reaction time of the marking system.

Calibration of the electronic circuitry is accomplished by moving the entire rotating portion of the machine out of the line of billet travel. A short test billet is placed into the test position. The probes are rotated while contacting the test billet, and the signals are recorded. The electronic circuit is then calibrated with simple dial adjustments.

The test billet contains four simulated seams produced by milling slots 0.76 mm (0.030 in.) deep with a 0.15 mm (0.006 in.) wide cutter. The locations of these milled-slot seams are on the flat, before the corner, on the corner, and after the corner.

Nondestructive Inspection of Tubular Products

Introduction

WROUGHT TUBULAR PRODUCTS are nondestructively inspected chiefly by eddy current techniques (including the magnetic flux leakage technique) and by ultrasonic techniques. In general, the eddy current and magnetic flux leakage techniques are applied to products not exceeding 1020 mm (40 in.) in diameter or 19 mm ($\frac{3}{4}$ in.) in wall thickness. On the other hand, ultrasonic inspection is used on tubes ranging from 3.2 to 2030 mm ($\frac{1}{8}$ to 80 in.) in diameter and from 0.25 to 64 mm (0.01 to $2\frac{1}{2}$ in.) in wall thickness. However, there are many exceptions, and the range of special techniques and applications associated with each inspection method is large. Most welded and seamless tubular products are nondestructively inspected by the manufacturer at the mill.

The many uses to which steel tubular products have been applied form a basis for classifying steel tubular products; for example, the terms casing, tube, and pipe are assigned on the basis of usage, as in water-well casing, oil-well tubing, and drill pipe. A second classification is based on methods of manufacture. Accordingly, all steel tubular products can be classified as either welded or seamless. A third classification applicable to special shapes can be considered subordinate to both of the general classifications above.

The major applications of the nondestructive inspection of tubular products are:

- Detection and evaluation of flaws
- Sorting of mixed stock
- Measurement of dimensions
- Comparative measurement of specific physical and mechanical properties

Of these, the primary application is the detection and evaluation of flaws. Sorting is often an auxiliary application employed for grade or size verification and can be based on chemical composition, dimensions, physical and mechanical properties, or other significant variables. A difficulty encountered in sorting arises when variables of little or no interest affect instrument indications to a greater degree than do the variables of interest. Several applications involving the measurement of dimensions and physical properties are described in this article. Others, such as the measurement of coating thickness and the noncontact measurement of wall thickness and variations in diameter, require highly specialized instrumentation and are discussed elsewhere in this Volume. Additional information on the inspection of pipe and pipelines, including the examination of field-welded girth welds, is available in the articles "Weldments, Brazed Assemblies, and Soldered Joints" and "Boilers and Pressure Vessels" in this Volume.

Nondestructive Inspection of Tubular Products

Selection of Inspection Method

The fundamental factors that should be considered in selecting a nondestructive inspection method, and in selecting from among the commercially available inspection equipment, are the product characteristics, the nature of the flaws, extraneous variables, rate of inspection, the end effect, mill versus laboratory inspection, specification requirements, equipment costs, and the operating costs.

Product Characteristics. Among the product characteristics that may affect the choice of inspection method and equipment are tube or pipe diameter, wall thickness, surface condition, method of fabrication, electrical conductivity, metallurgical condition, magnetic properties (notably permeability), and degree of magnetization.

Nature of Flaws. Both the nature of flaws and of potential but unallowable deviations from certain specified dimensions or properties have a bearing on the selection of inspection methods and equipment. The nature of flaws is often markedly influenced by the method of manufacture. For example, flaws in welded pipe are usually confined to the vicinity of the weld; therefore, an inspection procedure that is confined to the weld area may be adequate. If the welds are resistance welds, the most usual flaws are located in the weld plane and are in effect two-dimensional, having length and width but negligible thickness. On the other hand, if the welds are arc welds, porosity is the most usual flaw. In all welded tubular products, cracks are the most damaging flaws. In seamless tube, the location of flaws is not restricted, but may occur anywhere in or on the tube section.

Extraneous Variables. Many of the measurable variables in tubing and pipe are normal to the product and are not cause for rejection. These extraneous or harmless factors sometimes exert a greater effect on the inspection instrument than do the flaws that must be detected. For example, variations in magnetic permeability are common in steel and generate large signals in instruments that are permeability sensitive. However, the signals often are not pertinent to the test, nor are they cause for rejection. Surface scratches may be cause for rejection in some products and yet may be acceptable in others. Consequently, the inspection method and instrument selected must ignore or minimize variables that will not affect the utility of the part in its intended application.

The rate of inspection required is a major factor in the selection of an inspection procedure. When the value of the part or the hazard associated with its application justifies slow and thorough inspection, the procedure chosen is likely to be radically different from that selected for a mass-produced, low-cost product used in a noncritical application.

End Effect. In some applications, the only portions of the tube that are genuinely critical in its ultimate application are the ends. Unfortunately, with many nondestructive testing instruments, specific problems arise when inspection of the ends is required. End effect is encountered with the eddy current, ultrasonic, and radiographic methods. Consequently, inspection of the entire tube and the ends may require two different procedures; as a result, production speed is reduced and the total cost of inspection is correspondingly increased.

Mill Versus Laboratory Inspection. Although laboratory demonstrations of nondestructive inspection techniques may yield excellent results, subsequent mill performance may be entirely unsatisfactory because of conditions present in the mill that were not present in the laboratory.

Specification requirements may also affect the choice of inspection method and equipment. When the tubular product is covered by a flaw-size specification, all tubes with flaws larger than those specified must be rejected. However, tubes with flaws smaller than the specified rejection level should be accepted. Because many nondestructive inspection systems do not provide for linear adjustment or are incapable of making the required differentiation, this aspect of instrument performance must be carefully investigated.

Equipment cost is usually a major factor in the selection of inspection method and equipment. The initial cost of equipment may occasionally be minor, but in some cases installation may cost over \$1 million in basic and related equipment. The lowest-cost equipment may be for magnetic particle or liquid penetrant inspection; high-cost installations involve automatic flaw marking, classification of product based on flaw magnitude, computer analysis of results, multiple sorting levels, and many other convenience factors.

The operating cost of inspection procedures and equipment varies widely. In general, it is inversely proportional to the cost of the installation. The more expensive installations are usually completely automatic and are incorporated in a production line whose primary function is something other than inspection. Consequently, inspection adds little to total operating cost. In contrast, the lower-cost installations usually involve a separate operation and require the services of a highly trained, skilled operator.

Nondestructive Inspection of Tubular Products

Inspection of Resistance-Welded Steel Tubing

Resistance-Welded Steel Tubing

The diameters of resistance (longitudinal) welded steel tubing range from about 13 to 914 mm ($\frac{1}{2}$ to 36 in.); wall thicknesses, from 0.38 to 13 mm (0.015 to 0.5 in.). Tubing of intermediate and smaller diameters is produced on a draw bench.

Flaws that occur in resistance-welded steel tubing include cold welds, contact marks, cracks, pinholes, and stitching; these are described below. The terminology used to designate such flaws varies; the terms used in this article are those adopted by the American Petroleum Institute (API) (Ref 1).

Cold weld is the term widely used to indicate inadequate or brittle bonding with no apparent discontinuity in the fracture. Cold weld cannot be detected reliably by any nondestructive inspection method currently available.

Contact marks (electrode burns) (Fig. 1a) are intermittent imperfections near the weld line that result from miniature arcs between the welding electrode and the surface of the tube.

Fig. 1 Typical flaws in resistance-welded steel tubing. (a) Contact marks (electrode burns). (b) Hook cracks (upturned-fiber flaws). (c) Weld-area crack. (d) Pinhole. (e) Stitching. Views (c), (d), and (e) are mating fracture surfaces of welds.

Hook cracks (upturned-fiber flaws) (Fig. 1b) are separations within the base metal due to imperfections in the strip edge, which are parallel to the surface and turn toward the outside or inside surface when the edges are upset during welding.

Weld-area cracks (Fig. 1c) are any cracks in the weld area not due to upturned fibers.

Pinholes (Fig. 1d) are minute holes located in the weld line.

Stitching (Fig. 1e) comprises a regular pattern of light and dark areas that are visible when the weld is broken in the weld line. The frequency of variation usually corresponds to weld-current variation. Increased use of ultrahigh-frequency current for welding has minimized the occurrence of stitching.

The nondestructive inspection of resistance-welded tube can be performed continuously on a welding machine or on individual lengths at any stage of processing. When performed on a welding machine, test indications can be used to guide the welding-machine operator in making machine adjustments.

Eddy Current Inspection

In 1929, H.C. Knerr initiated the development of eddy current inspection for Republic Steel Corporation. In 1930, in conjunction with Knerr, C. Farrow demonstrated the detection of flaws in a brass tube by the phase shift in eddy currents generated in the tube. In 1931, he demonstrated that the phase-shift concept could be applied to magnetic steel tube, provided the area being inspected was magnetically saturated (Ref 2). The eddy current inspection method replaced both hydrostatic and pneumatic pressure testing of resistance-welded tubing because of its superiority in detecting weld imperfections. Several of these typical weld imperfections are shown in Fig. 2.

Fig. 2 Mating fracture surfaces of pipe or tube welds showing imperfections detectable by eddy current inspection but not by pressure testing. (a) Unwelded spot (diagonal arrows) and a nonpenetrating pinhole (horizontal arrows). (b) Unwelded spots, probably caused by entrapped foreign matter. (c) Surface crack in weld

At present, the eddy current methods are probably the most widely used for the inspection of welded steel tubing in diameters up to 75 mm (3 in.), although these methods are not limited to the smaller diameters. In welded tubing, most flaws occur in or near the longitudinal-welded seam, and in most cases a test of a narrow band including the seam is adequate. This makes possible the use of small eddy current probe coils tangent to the seam area, eliminating the diameter limitation. Tubes with diameters up to 406 mm (16 in.) are currently being inspected in production by this method.

Eddy current inspection is usually on tubing having wall thicknesses less than 3.2 mm ($\frac{1}{8}$ in.), but successful production testing has been reported on tubing having wall thicknesses to 13 mm ($\frac{1}{2}$ in.) (Ref 3). Most eddy current tests use differential systems and therefore are most sensitive to flaws that involve a marked change in normal electrical characteristics. If the flaw is of considerable length and of uniform characteristics, it is sometimes necessary to use special arrangements for its detection. Small probe coils continuously compare the weld zone with the base metal, thus revealing the existence of the elongated or long flaw.

When inspecting for shallow-cracklike surface flaws 3.2 mm ($\frac{1}{8}$ in.) or less in depth, relatively close correlation between crack depth and signal magnitude has been obtained with a single coil arrangement without magnetic saturation (Ref 4). However, the limited penetration of this arrangement and its need for a surface opening for depth evaluation limit its usefulness.

The speed of inspection by eddy current methods depends in part on many factors, including the size of the flaw that must be detected, the discriminating ability of the circuit used, end-inspection requirements, and the speed of response of the signal circuit. The mathematical relationship of the test-current frequency and linear speed may automatically limit the size of flaw that can be detected. Speeds of 305 m/min (1000 sfm) have been recorded, but the usual speed is 45 to 90 m/min (150 to 300 sfm).

Weld Twist. When using probe coils in eddy current inspection, the twist in the weld sometimes causes a special problem. When the weld twists out of the zone of high sensitivity, the effectiveness of flaw detection is markedly

reduced. The problem cannot be solved by increasing the size of the arc segment covered by the probe coil, because this arrangement also reduces sensitivity. One solution involves the use of a series of small probe coils, staggered with respect to the weld line, to ensure continuous coverage (Ref 5, 6). The problem has also been solved in some installations by taking advantage of the electromagnetic difference that exists between the weld zone and the base metal. Special probe coils respond to this difference and automatically rotate the test head or the tube until the weld zone is properly located with respect to the probe coil.

End effect, caused by abrupt changes in the magnetic field, becomes a problem whenever cut lengths are inspected. Various auxiliary circuits, ranging widely in effectiveness, have been developed for suppressing end effect to permit satisfactory inspection closer to the end of the tube. End effect can be minimized by keeping the tube ends in contact as they move through the test coils.

Mechanical variables that may affect inspection results include transverse movement of the tube in the test coil and changes in temperature or linear speed. The contribution of these factors to test results is sometimes difficult to determine in the laboratory, but they may create serious problems in production testing.

Equipment costs for eddy current inspection can vary widely, depending on the extent of refined circuitry, automatic handling and sorting equipment, computer analyzers, or special auxiliary equipment that may be needed.

The operating costs of a well-designed eddy current system are among the lowest of any nondestructive inspection method. After the system has been properly adjusted, it can be operated by unskilled workers. When automatic marking is provided, the inspection can frequently be combined with another operation without appreciably increasing the cost of the latter operation.

Advantages and Limitations. All flaws in resistance welds except cold weld, are readily detected by eddy current methods. Cold weld is by far the most difficult of all flaws to detect by any of the nondestructive inspection methods. Although the other types of flaws listed above can be detected by eddy current methods, it should not be inferred that all eddy current instruments will detect all of these flaws. The range of capabilities of commercial eddy current instruments is extensive, and conclusions regarding their capabilities often require actual tests. Because eddy current test coils may either surround or be adjacent to the tube being tested, the variety of coil designs, arrangements, and combinations constitutes another major group of variables affecting equipment capabilities. In general, eddy current instruments have the advantages of speed in testing and convenience in operating, marking, and sorting. Perhaps their most universal disadvantage is their inability to inspect completely to the ends of tubes. Additional information is available in the articles "Eddy Current Inspection" and "Remote-Field Eddy Current Inspection" in this Volume.

Flux Leakage Inspection

Flux leakage (or magnetic field perturbation) inspection is similar to eddy current inspection but requires magnetization of the tube and is limited to the inspection of ferromagnetic materials. When the tube is magnetized to near saturation, the magnetic flux passing through the flaw zone is diverted by the flaws. Detectors of various types detect the diverted flux when either the detector or the tube is moved in a direction that causes the detector to cut through the diverted flux. This in turn produces a signal to reveal the presence of the flaw.

Various means are used to magnetize the tube. A current-carrying conductor inside the tube produces a circular magnetic field, magnetizing the tube in a circumferential direction. The magnetic flux is diverted by the longitudinal component of any flaws in its path. The probe, moving through the diverted flux, generates a signal roughly proportional to the size of the flaw. On a longitudinal-welded seam, an electromagnet with pole pieces on each side of the weld can be used to magnetize the weld area, with flux passing transversely across the seam. The magnetic flux is diverted by the longitudinal component of any flaw in the weld, and the flaw can be detected electronically. To detect transverse flaws, the tube may be magnetized longitudinally by an encircling conductor. The flux is then diverted by the transverse component of any flaw present, and the probe moving through the diverted or leakage flux reveals the presence of the flaw.

Hall probes are the detectors ordinarily used. In all applications, there must be relative movement between the probes and the diverted flux so as to generate a signal and to indicate the presence of a flaw. The relative motion can be achieved by rotating or oscillating either the tube or the probes. As in eddy current inspection, various types of instrumentation have been developed and are available commercially (Ref 7, 8, 9, 10).

Limitations. Because of the nature of the flux leakage test, tube diameter is not a limitation, but the wall thickness that can be tested is limited by the ability of the magnetic flux to penetrate the wall and the ability of the sensor to sense flaws at a distance from the wall. Production applications have been used on tubing having wall thicknesses up to 25 mm (1 in.), but 7.6 mm (0.3 in.) is the usual limit. At wall thicknesses in excess of 7.6 mm (0.3 in.), sensitivity becomes a serious problem. However, current developments are improving capabilities in testing thick walls (Ref 8, 9, 10).

Although the flux leakage method usually detects flaws that are longitudinally oriented, the principle of the flux leakage method can be used in the design of equipment for detecting transverse flaws. Pinholes, with minimal longitudinal dimensions, and subsurface flaws are difficult to detect. For reliable detection of isolated pinholes, the pitch of the helical inspection path must be small, and the production rate is correspondingly limited. Sensitivity to subsurface flaws drops rapidly as the flaws are located farther from the surface. To detect inside-surface flaws such as cracks and gouges, flux leakage equipment requires special design features for reliable quantitative evaluation.

Speed of inspection is a function of the dimensions of the elements involved and the maximum tolerable length of flaw. Because the tube or the probe must be rotated or oscillated, only a helical or zigzag path is inspected, and the pitch of the helix or the distance between reversals must be less than the maximum tolerable length of flaw. When the tube must be fed over a central conductor for magnetization and then removed for inspection, high-speed production is hindered. The use of multiple probes reduces the actual testing time in proportion to the number of probes, but the time required to feed the tube over the conductor remains constant. Such installations are operated in production at speeds as high as 15 m/min (50 sfm). Installations using external magnetization are reported to operate at speeds to 60 m/min (200 sfm).

Weld twist presents a problem in any installation in which only the weld is inspected. In flux leakage inspection, the problem is solved by increasing the magnitude of the arc covered by the oscillating probe.

End Effect. As in eddy current inspection, the error caused by end effect can be minimized by butting the ends of the tubes together during the test.

Mechanical conditions, such as tube ovality, variations in linear speed, and transverse movement of the tube, have adverse effects on the test results and must be controlled.

Equipment Costs. As with eddy current equipment, the cost of equipment for flux leakage inspection varies. An elementary unit costs slightly more than a comparable eddy current unit because of the need for rotating devices. The addition of auxiliary equipment, such as automatic markers, recorders, computer analyzers, and special handling devices, markedly increases cost.

Operating costs, which are relatively low, depend on the degree of automation and the degree to which the inspection can be combined with other operations. Flux leakage tests can sometimes be combined with another operation--for example, welding. As the tube emerges from the welding operation, it enters the field of the electromagnetic yoke (Fig. 3), which generates a flux in the weld area. The oscillating probe detects any flux diverted by a flaw in the weld. In most cases, however, the need for movement of the probe through the diverted flux makes the combination less desirable than systems with no moving parts.

Fig. 3 Setup for the flux leakage inspection of welded steel tubing

inspection). They are rotated as they pass longitudinally through a glanded immersion tank. The immersed transducers must be carefully selected for tube diameter, wall thickness, and type of imperfection to be located. The transducer, focal length, response to outside diameter and inside diameter calibration notches, instrumentation pulse rate, gate adjustment for flaw alarm, and speed of tube travel are all variables to be taken into consideration. Inspection is usually performed slowly (~ 0.9 m/min, or 3 sfm). Tubes must be clean, straight, round, and of uniform dimensions. All types of flaws that commonly occur in resistance welds, except cold weld, can be detected by ultrasonic inspection.

Most ultrasonic inspection of resistance-welded tubing is restricted to the weld zone and is performed immediately after the welding operation. Components and adjustments for inspecting the weld must be carefully selected and accurately controlled. The transducer must be appropriate for the size and type of flaws to be detected. Focused transducers are generally preferred. The shear-wave angle must be selected for the best evaluation of imperfections. The angle often used is 45° , but tests have revealed that angles between 50 and 70° yield signals more directly proportional to the area of flaws in the weld plane (Ref 3, 11).

In the inspection of pipe, provision must be made to maintain the spacing between the transducer and the pipe constant within close tolerances as the pipe moves past the transducer. The couplant should preferably be continuously delivered to the surface of the pipe through openings in the transducer mounting. Coupling through a water jet is also used. Particular attention should be given to the detection of short flaws. Some ultrasonic pipe-inspection equipment will not detect flaws shorter than 6.4 mm ($\frac{1}{4}$ in.), which will not satisfy the inspection requirements for most resistance-welded pipe.

A disadvantage of the ultrasonic method in tube inspection is its high sensitivity to minor scratches and to elongated dimensional changes, such as the ridge left when the weld flash is not completely removed or rolled down. However, proper selection of inspection equipment can minimize this problem (Ref 11). An important development is the wheel-type search unit. The transducer of the wheel-type search unit is mounted on the axle of a liquid-filled wheel and is held in a fixed position as the wheel rotates. The surface of the wheel is flexible and adapts itself to the surface condition of the tube as it rolls over it. A small amount of liquid couplant, usually water, is required between the surface of the wheel tire and the surface of the tube. This arrangement provides most of the advantages of immersion testing without the necessity of immersing the tube.

Speed of inspection is limited by the pulse rate of the ultrasonic equipment and by the maximum length of a tolerable imperfection. Speeds as high as 69 m/min (225 sfm) have been reported, but unless multiple inspection heads are used, speed is ultimately dependent on the rejectable flaw size.

Ultrasonic Inspection

Ultrasonic inspection is one of the most widely used methods for inspecting tubular products (see the article "Ultrasonic Inspection" in this Volume). Widespread use of the ultrasonic method on tubular products was made practical by the development of angle-beam shear-wave testing, immersion testing, and focused transducers. As with the eddy current and flux leakage methods, ultrasonic inspection can be applied either to the entire tube or to the weld only.

Ultrasonic inspection of the entire welded tube is usually limited to small-diameter, drawn products, in which the weld cannot easily be distinguished from the remainder of the tube. The tubing may have a diameter as small as 3.2 mm ($\frac{1}{8}$ in.) and a wall thickness of only 0.25 mm (0.01 in.). These small products are usually inspected while immersed in water (immersion

Weld twist can present a problem; as the weld twists away from the critical location, transducer sensitivity drops sharply. To maintain the weld and the transducer in the correct mechanical relationship, the weld can be positioned automatically by the use of an electromagnetic control.

End effect, although less of a problem than in eddy current inspection, is a factor in ultrasonic inspection, and supplementary testing may be necessary if inspection of the tube ends is critical. The supplementary test can be made with ultrasonic equipment of special design.

Mechanical variables are critical in contact ultrasonic testing. Spacing between the transducer and the surface of the tube, angle of transducer, and sidewise movement of tube must be accurately controlled. These variables can sometimes be better controlled in immersion testing.

The equipment costs of ultrasonic inspection equipment are highly dependent on the amount of auxiliary equipment included. Accessories such as automatic marking devices, computer analyzers, and material-handling equipment can markedly increase equipment costs, especially for the inspection of heavy pipe.

The operating costs of ultrasonic inspection, in accord with other inspection methods, depend on whether inspection is operated separately or combined with another operation. For example, if inspection is incorporated into the welding line, an inspector usually is not required, and the operating costs are minimal.

Example of Practice. Details of an ultrasonic inspection procedure applied to resistance-welded stainless steel tubing that was used to clad nuclear fuel elements are given in the following example.

Example 1: Ultrasonic Inspection of Welded Type 304 Stainless Steel Tubing Used To Clad Nuclear Fuel Elements.

The ultrasonic method, employing the immersion pulse-echo shear-wave technique, was used in the inspection of resistance-welded type 304 stainless steel tubing that was used as cladding for nuclear fuel elements. A typical tube size was 9.88 ± 0.013 mm (0.389 ± 0.0005 in.) ID and 0.419 mm (0.0165 in.) $\pm 5\%$ wall thickness. A standard length was 4.6 m (15 ft), and the tubing was inspected in the 10 to 15% cold-worked condition.

The reference standard, which was a tube selected from the same production lot as that inspected, contained longitudinal and transverse notches, 1.59 mm (0.0625 in.) long by 0.041 mm (0.0016 in.) deep by 0.10 mm (0.004 in.) wide, prepared by electrical discharge machining, in outside and inside walls.

Test Conditions. The tubing, in a clean and dry condition, was inspected before being cut to final length. The tubing was propelled through an immersion water tank on a preselected helix by a variable-speed drive. Throughput speed was 2.4 m (8 sfm). The tubing was rigidly supported to maintain accurate alignment between tubing and search unit.

Direction of Testing. Normally, testing was conducted in two directions only--one a circumferential mode, searching for longitudinal outside or inside notches, and the other a longitudinal mode, searching for circumferential or transverse notches. When required, two additional searches and search units were employed to search in directions opposite to those mentioned. Proper balance between outside and inside notches was obtained by careful alignment of search units and gate adjustments on the CRT.

Search Units. Focused search units, using either spherical or cylindrical transducers, were used. Frequencies ranged from 3.8 to 4.8 MHz, and the active beam profile was equal to, or shorter than, the notch length, thus ensuring the most reproducible test. The search unit in the longitudinal direction operated at a frequency of 3.8 MHz with a cylindrical line focus of 1.1×0.51 mm (0.045×0.020 in.). The search unit in the transverse direction operated at 4.8 MHz with a focus of 0.89×0.51 mm (0.035×0.020 in.). Commercially available electronic equipment with a pulse rate of at least 5 kHz, a gated alarm, and a pulse-stretching circuit was used. Readout was by a chart recorder.

Magnetic Particle Inspection

The principal use of the magnetic particle method in the inspection of resistance-welded pipe is largely limited to the inspection of pipe ends. In some pipe applications, the ends of the pipe are the sections most critically loaded, and magnetic particle inspection of the ends supplements inspection of the remainder of the pipe by other methods. In the past, the method was widely used to inspect the entire area. However, its inability to detect significant subsurface flaws,

even when the magnetic particles are coated with a fluorescent, and its dependence on human vision and judgment led to its replacement by eddy current and ultrasonic methods. The magnetic particle method is still used in the mill to help establish the precise location of flaws previously detected by other inspection methods. Additional information is available in the article "Magnetic Particle Inspection" in this Volume.

Liquid Penetrant Inspection

Liquid penetrants (visible-dye and fluorescent) are ordinarily used on nonferromagnetic materials, which constitute only a small fraction of resistance-welded tubular products. Testing speeds are extremely slow, and use of these methods can be justified only when the hazard involved in end use justifies extreme inspection precautions. In such cases, the penetrant methods usually supplement other methods. Additional information is available in the article "Liquid Penetrant Inspection" in this Volume.

Radiographic Inspection

Radiographic methods of inspection cannot be used successfully on the longitudinal seam of resistance-welded pipe, because the predominant flaws are essentially two dimensional and have little or no effect on the radiographic film. However, when the ends of resistance-welded pipe are butt welded together, arc welding is frequently used, and the method normally used to inspect arc-welded joints is radiography. Additional information is available in the articles "Radiographic Inspection," "Industrial Computed Tomography," and "Neutron Radiography" in this Volume.

Nondestructive Inspection of Tubular Products

Inspection of Double Submerged Arc Welded Steel Pipe

Double Submerged Arc Welded Steel Pipe

Most arc-welded tubular products are produced by the double submerged arc process, in which the seam is welded in two passes, one on the outside and the other on the inside. Tube and pipe diameters range from 457 to 2030 mm (18 to 80 in.), and wall thicknesses from 6.4 to 19 mm ($\frac{1}{4}$ to $\frac{3}{4}$ in.). Nondestructive inspection is usually confined to the weld area.

Flaws. Some of the flaws usually encountered in double submerged arc welds are incomplete fusion, incomplete penetration, offset of plate edges, out-of-line weld beads, porosity, slag inclusions, and weld-area cracks (Ref 1). These flaws are illustrated in Fig. 4 and described below.

Fig. 4 Typical flaws in double submerged arc welded steel pipe. (a) Incomplete fusion. (b) Incomplete penetration. (c) Offset of plate edges. (d) Out-of-line weld beads (off seam). (e) Porosity (gas pocket). (f) Slag inclusions. (g) Weld-area crack

Incomplete fusion (Fig. 4a) is a lack of complete coalescence of some portion of the metal in a weld joint.

Incomplete penetration (Fig. 4b) is a condition in which the weld metal does not continue through the full thickness of the joint.

Offset of plate edges (Fig. 4c) is the radial offset of plate edges in the weld seams.

Out-of-line weld beads (off-seam) (Fig. 4d) is a condition in which the inner or outer weld beads, or both, are sufficiently out of radial alignment with the abutting edges of the joint to cause incomplete penetration.

Porosity (gas pocket) (Fig. 4e) consists of cavities in a weld caused by gas entrapped during solidification. Porosity may occur as subsurface or surface cavities.

Slag inclusions (Fig. 4f) are nonmetallic solid material trapped in the weld deposit or between weld metal and base metal.

Weld-area cracks (Fig. 4g) are cracks that occur in the weld deposit, the fusion line, or the heat-affected zone.

Radiographic Inspection

Film x-ray was the first nondestructive inspection method applied to the quality control of double submerged arc welded steel tubular products. The film technique was expensive and was subsequently replaced by the image intensifier with fluorescent screen, an arrangement that requires the inspector, stationed in a darkened room, to observe the fluorescent screen continuously while the pipe travels over the x-ray tube. Rejection of the pipe depends on an appraisal of the degree of darkness registered on the screen. This method is still in use but is being supplemented, and sometimes replaced, by ultrasonic inspection.

Limitations. In addition to high cost and dependence on the human factor, a lesser capacity for discrimination is another important reason for the replacement of x-ray radiographic techniques by ultrasonic inspection methods. Radiography is sensitive to flaws only when the flaws significantly alter the ability of the material to absorb radiation; this usually occurs when a flaw changes the effective metal thickness by 2% or more or when the flaw causes a change in density equivalent to at least a 2% change in metal thickness. The technique is sensitive to small gas pockets but is relatively insensitive to tightly closed cracks (Ref 12). Because cracks, especially those on the surface, are much more damaging than small totally embedded gas pockets, it is often essential to supplement radiographic inspection with another method that is more sensitive to cracks (Ref 13).

Speed of inspection by the continuous radiographic method depends on the eyesight, alertness, and judgment of the inspector and is usually in the range of 3 to 9 m (10 to 30 sfm).

Weld Twist. Because of the thick cross section and the width of the weld bead characteristic of double submerged arc welded steel pipe, weld twist is usually not a problem.

End effect is an important consideration. Consequently, most specifications require that the continuous radiographic inspection of pipe ends be supplemented by magnetic particle inspection, film x-ray inspection, or both.

Equipment Costs. Most of the expenditure is directed toward the mechanical arrangements needed for handling the large-diameter, thick-wall product. Precise positioning, uniform linear speed, and convenient controls for slowing speed to inspect flaw indications are essential for satisfactory inspection.

The operating costs of continuous radiographic inspection are comparatively high because of the slow speeds and the need for two operators in most installations.

Ultrasonic Inspection

In the ultrasonic inspection of double submerged arc welded pipe, the excess bead at the welded seam presents a problem in that the edges of the bead generate false indications. On the other hand, the excess bead provides a guide for maintaining the inspection head in the correct position as it tracks the weld. One solution to the problem of extraneous reflections is the use of two search units, each with two or more focused transducers and appropriate electronic accessories (Ref 14). In this method, the pipe moves into the testing station and is brushed and prewetted. An optical system locates the weld precisely. As the pipe moves forward, the two search units are lowered into the test position. As the end of a pipe leaves the tester, the search units are automatically raised from the pipe. The transducers are positioned to produce shear waves at an angle of approximately 70° in the pipe. The electronic controls are adjusted so that part of the weld zone and a 25 mm (1 in.) wide band of adjacent strip are inspected by each search unit. The inspected portions of the weld zone overlap to ensure thoroughness of inspection. Flaws exceeding a predetermined standard automatically operate the appropriate marker.

The ultrasonic method is not as sensitive to gas pockets as the radiographic method but is much more sensitive to tightly closed cracks. Such cracks can be detected even when they are located at the junction of the weld bead and the base metal.

Nondestructive Inspection of Tubular Products

Arc-Welded Nonmagnetic Ferrous Tubular Products

Austenitic stainless steel and other nonmagnetic ferrous tubular products are, except for seamless tubing, usually fabricated from plate, sheet, and strip by forming and arc welding, frequently by the gas tungsten-arc process. The weld flaws encountered are similar to those found in double submerged arc welded products, except for those resulting from deposition of the second bead. Although tube diameters range from 3.2 to 762 mm ($\frac{1}{8}$ to 30 in.) and wall thicknesses from 0.10 to 9.53 mm (0.004 to 0.375 in.), the small-diameter, thin-wall products predominate. Tubes having diameters from about 3.2 to 102 mm ($\frac{1}{8}$ to 4 in.) are produced on a draw bench.

Eddy Current Inspection. Although the austenitic stainless steels are nominally nonmagnetic, some of these alloys will develop magnetic constituents (notably ferrite) in the weld fusion zone and in cold-worked areas, thus causing variations in permeability. Consequently, magnetic saturation is required for the reliable eddy current detection of small flaws in the weld zones of these alloys. In addition, because of their lower electrical conductivity, stainless steels require higher frequencies than those used for the eddy current inspection of carbon steels. In other respects, the practices employed in eddy current inspection are the same as those applied to carbon steel products.

Because diameters in the range of 3.2 to 75 mm ($\frac{1}{8}$ to 3 in.) account for most of welded stainless steel tube production, encircling inductor and detector coils can be used in inspection. Usually, the coils are close fitting, with an allowable maximum clearance of only 1.6 mm ($\frac{1}{16}$ in.). The entire tube is inspected. For calibration purposes, a hole drilled through the tube wall is ordinarily used. Allowable flaws are described in ASTM A 450. In general, inspection speeds range from 7.6 to 46 m/min (25 to 150 sfm), although speeds up to 140 m/min (450 sfm) have been attained.

Ultrasonic inspection is performed on tubes ranging from 3.2 to 762 mm ($\frac{1}{8}$ to 30 in.) in diameter with wall thicknesses ranging from 0.10 to 9.52 mm (0.004 to 0.375 in.). Barium titanate, lithium sulfate, quartz, or lead zirconate can be used as the transducer element; operating frequencies range from 2.25 to 15 MHz. In general, the pulse-echo shear-wave technique is used with immersed, focused transducers. For larger-diameter tubes, where the size can cause practical difficulties in immersion and where the curvature of the tube is slight, flat crystals with conventional contact coupling can be used. In immersion testing, the shear-wave angle in the testpiece ranges from 45 to 70°.

When the application is critical, ultrasonic inspection must be supplemented by other methods, such as eddy current and liquid penetrant inspection. On larger-diameter tubing, only the weld is tested. Usually, the transducer is stationary and the tube is moved axially. With smaller-diameter tubing, the entire tube is tested. The transducer is usually stationary while the rotating tube is moved axially. The pitch of the helix inspected is a function of the maximum length of the flaw that can be tolerated. The calibration tube contains one or more milled slots, as required by the applicable specification.

Production rate depends largely on the amount of metal being inspected--that is, the weld zone only or the entire tube--and can range from a few inches to about 1.5 m/min (5 sfm). Speeds as high as 6 m/min (20 sfm) have been attained.

Liquid Penetrant Inspection. Penetrants used for the inspection of tubing may be either the fluorescent or nonfluorescent (visible-dye) type. The fluorescent penetrants may be water soluble or an emulsion. For a reliable test, the tube must always be cleaned before testing. Because the appraisal of flaws is based on visual judgment, inspection is usually restricted to the outside surface unless the tube is large enough and short enough to permit inspection of the inside surface. Production rate is highly dependent on the mechanical handling facilities available and ranges from a few inches per minute to as much as 3 m/min (10 sfm).

Radiographic Inspection. Some users specify that film x-ray must be used (Ref 15). Radiography is used to inspect tubes ranging in diameter from 6.4 to 762 mm ($\frac{1}{4}$ to 30 in.) and in wall thickness from 0.64 to 9.53 mm (0.025 to 0.375 in.). Calibration is by penetrometer. Either the tube or the tester may move with respect to the other. The usual flaw detection difficulties associated with radiography are compounded with the smaller diameters because the x-ray beam must pass through two wall thicknesses. Production speed ranges from the average of a few inches per minute to as much as 3.7 m/min (12 sfm).

Nondestructive Inspection of Tubular Products

Continuous Butt-Welded Steel Pipe

Most carbon steel pipe is produced by a process that continuously forms hot strip (skelp) into tubular shape, then passes it through a welding horn and welding stand, where the edges are pressed firmly together and pressure welded to provide the longitudinal seam. The strip ends are flash butt welded together without stopping the line, thus making the process truly continuous. A multiple-stand stretch-reducing mill brings the welded pipe to its finished size. As the name implies, this mill is used for reducing the diameter of the pipe being produced by simultaneously applying pressure and tension.

Pipe diameters range from 22 to 114 mm ($\frac{7}{8}$ to $4\frac{1}{2}$ in.) and wall thicknesses from 1.9 to 12.7 mm (0.076 to 0.500 in.).

The inspection of continuous butt-welded pipe is directed primarily toward in-plant quality control, although it is required by some specifications. The eddy current method is employed almost exclusively and is applied not only to cold pipe but also to hot pipe at a temperature above the Curie point. Encircling inductor coils and differentially wound detector coils are used with a coil-to-pipe spacing of 6.4 mm ($\frac{1}{4}$ in.) or less and an operating frequency of 2.5 kHz. A saturating field of about 70,000 ampereturns is required for cold pipe, which is nonmagnetic at temperatures above the Curie point. The coil assembly for hot pipe must be water cooled and encased in heat-resistant material (Ref 16). Marking the hot pipe requires a special high-temperature paint.

The eddy current inspection setup is usually calibrated to reject all flaws, internal and external, that extend more than $12\frac{1}{2}$ % through the wall. The calibration standard is usually a drilled hole.

The speed of inspection corresponds with the speed of the mill and, for cold pipe, ranges from 53 to 150 m/min (175 to 500 sfm). Higher speeds are employed for inspecting hot pipe.

Nondestructive Inspection of Tubular Products

Spiral-Weld Steel Pipe

Spiral-weld steel pipe is made principally in large diameters and is a relatively low-production product. The pipe is either resistance or submerged arc welded.

Resistance-welded pipe is inspected by either the eddy current or the ultrasonic method. The ultrasonic or radiographic method is used to inspect submerged arc welded pipe. Usually, the ends of pipe welded by either process are also inspected by a supplementary technique, such as film x-ray or magnetic particle inspection.

Nondestructive Inspection of Tubular Products

Seamless Steel Tubular Products

Steels melted by various processes can be successfully converted into seamless tubes. In general, killed steels made by open-hearth, electric-furnace, and basic-oxygen processes are used. Because of the severity of the forging operation involved in piercing, the steels used for seamless tubes must have good characteristics with respect to both surface and internal soundness. A sound, dense cross section, free from center porosity or ingot pattern, is the most satisfactory for seamless tubes. Metallurgical developments have contributed greatly to the improvement of steels for seamless tubes; as a result, the seamless process has been extended to include practically all of the carbon and alloy grades of steel.

Flaws in seamless tubular products may occur at any point on the outside and inside surfaces or within the tube wall (Ref 1). The flaws usually encountered are blisters, gouges, laminations, laps, pits, plug scores, rolled-in slugs, scabs, and seams. These are illustrated in Fig. 5 and described below.

Fig. 5 Typical flaws in seamless tubing. (a) Blister. (b) Gouge. (c) Lamination. (d) Lap (arrow). (e) Pit. (f) Plug scores. (g) Rolled-in slugs. (h) Scab. (i) Seam (arrow)

Blisters (Fig. 5a) are raised spots on the surface of the pipe caused by the expansion of gas in a cavity within the wall.

Gouges (Fig. 5b) are elongated grooves or cavities caused by the mechanical removal of metal.

Laminations (Fig. 5c) are internal metal separations creating layers generally parallel to the surface.

Laps (Fig. 5d) are folds of metal that have been rolled or otherwise worked against the surface but that have not been fused into sound metal.

Pits (Fig. 5e) are depressions resulting from the removal of foreign material rolled into the surface during manufacture.

Plug scores (Fig. 5f) are internal longitudinal grooves, usually caused by hard pieces of metal adhering to the mandrel, or plug, during plug rolling.

Rolled-in slugs (Fig. 5g) are foreign metallic bodies rolled into the metal surface, usually not fused.

Scabs (Fig. 5h) are flaws in the form of a shell or veneer, generally attached to the surface by sound metal. Usually, scabs originate as ingot flaws.

Seams (Fig. 5j) are crevices in rolled metal that have been closed by rolling or other work but have not been fused into sound metal.

Ultrasonic inspection is probably the method most commonly used on seamless tubular products, which range from 3.2 to 660 mm ($\frac{1}{8}$ to 26 in.) in diameter and from 0.25 to 64 mm (0.01 to $2\frac{1}{2}$ in.) in wall thickness. The tube, while rotating, is usually moved longitudinally past the transducers, thus providing inspection along a helical path. In a typical installation, six transducers inspect the rotating tube as it progresses through the machine. Four transducers are below the tube and are coupled to it by water columns; two transducers are above the tube and make contact through fluid-filled plastic wheels. This machine is capable of handling tubes ranging from 50 to 305 mm (2 to 12 in.) in diameter.

As with welded tubing, the smaller diameters of seamless products are inspected while immersed, and the larger diameters are inspected by direct contact. Transducer crystals may be quartz, lithium sulfate, barium titanate, or lead zirconate. The frequency ordinarily used is 2.25 MHz. The transducer may or may not be focused, depending on the tube diameter and the nature of the flaws anticipated. In most cases, the ultrasonic shear-wave angle is 45° but may be as large as 70° . The usual couplant is water, but oil is sometimes used.

Because all installations involve rotation of either the tube or the transducers, the inspection invariably follows along a helical path. The pitch and width of the helical path vary widely, depending on the characteristics of the equipment and the specifications to be met. The pitch is usually between 9.5 and 13 mm ($\frac{3}{8}$ and $\frac{1}{2}$ in.), which translates to two to three revolutions per each 25 mm (1 in.) of longitudinal travel. Almost all forms of visible and audible alarms, as well as automatic recorders, are used with the ultrasonic equipment.

All types of flaws in seamless tubes can be detected by ultrasonic methods, but the minimum flaw dimensions, the degree of sensitivity, the flexibility of adjustment, and the accuracy of calibration all vary widely with the basic instrumentation and the supplementary components chosen. The flaw used most frequently for calibration is a longitudinal slot. The depth of slot may vary from 3 to $12\frac{1}{2}$ % of the wall thickness, depending on the end use of the product and the specification involved. The length of the slot may be as much as 38 mm ($1\frac{1}{2}$ in.) but is usually specified as twice the width of the transducer. Widths of slots should be kept at a minimum and should never exceed twice the depth. The frequency of calibration checks depends on the criticality of the tube application. In a few cases, a calibration check is required after every tube, but once every 4 h of production is usually considered adequate.

Speed of inspection also varies widely, depending on many variables, especially the maximum tolerable length of flaw and the number of transducers used. The current range of inspection speed is 0.6 to 46 m/min (2 to 150 sfm); the upper limit can be increased by increasing the number of transducers. The following example describes the setup used for the ultrasonic inspection of stainless steel tubular products, with special emphasis on the calibration procedures used for flaw detection.

Example 2: Ultrasonic Inspection of Seamless and Welded Austenitic Stainless Steel Tubular Products.

Seamless and welded austenitic stainless steel tubular products were inspected by ultrasonics, using a system that rotated and moved the pipe or tube past a stationary ultrasonic search unit. The system was equipped to inspect by either contact

or immersion. The inspection unit contained a rotational and longitudinal drive mechanism and a relatively small open-ended and glanded immersion tank through which the tube or pipe passes (Fig. 6). The tank also contained the search units.

Fig. 6 Unit used for the ultrasonic inspection of seamless and welded stainless austenitic steel tubular products. A, tube being inspected; B, immersion tank; C, drive wheels; D, search-unit tube; E, drive mechanism. Inset shows lateral displacement of the search unit for circumferential inspection to detect longitudinal flaws.

To inspect, a reference tube or pipe was usually first placed in the unit. The reference tube or pipe was of a convenient length (usually 1.2 to 1.8 m, or 4 to 6 ft) and similar in type, size, and wall thickness to the product to be inspected. The reference tube contained notches in both outside and inside walls. Generally, the depth of the notches varied from 3 to $12\frac{1}{2}\%$ of the wall thickness, with the shallower notch being used for seamless tube and the deeper notch for welded tube. Most notches ran in the longitudinal direction and were approximately 25 mm (1 in.) long. Typically, the width of a notch was not more than twice its depth. In some cases, transverse notches were used as well as longitudinal notches. The dimensions of the transverse notch were the same as those of the longitudinal notch. The depth of notches was never less than 0.10 mm (0.004 in.).

With the reference standard placed in the inspection unit, suitable search units were selected. For the detection of longitudinal flaws, a line-focused search unit was generally used. The focal length varied from approximately 25 to 114 mm (1 to $4\frac{1}{2}$ in.). The short focal length was used for small-diameter tubing, and the longer focal tubing length was used for larger-diameter tubing. The length of the beam (lined up with respect to the longitudinal axis of the tube or pipe) varied from approximately 6.4 to 25 mm ($\frac{1}{4}$ to 1 in.). The length of the beam used depended on the size of the flaw to be detected. Shorter beam lengths were used to detect smaller (shorter) flaws. A beam 13 mm ($\frac{1}{2}$ in.) long was normally used. To detect transverse flaws, a spherically focused search unit could be used in addition to a line-focused unit.

The search unit was centered with respect to the reference tube, ensuring that a water gap between the search unit and the tube was equal to the focal length of the search unit minus the radius of the tube. Angular adjustment and positioning were performed to obtain a maximum response from the tube wall indicative of proper centering. For circumferential inspection to detect longitudinal flaws, the search unit was displaced laterally or set off from the center of the tube to obtain the proper angle at which the sound would travel through the tube wall (inset, Fig. 6). Generally, inspection was performed using a shear wave traveling at an angle of 45° around the tube. The offset distance required was calculated using the formula:

$$L = (D/2)(v_w/v_m) \sin \theta \quad (\text{Eq 1})$$

where L is the offset distance, D is the diameter of the tube or pipe, v_w is the velocity of sound in water, v_m is the velocity of sound in the tube, and θ is the desired refracted angle in the tube or pipe. The value for the velocity of sound in the tube depended on whether a longitudinal or shear wave was to be used. The offset value obtained from Eq 1 was an approximation. The actual amount of offset was adjusted from that calculated to obtain best presentation and equalization of responses from outside and inside notches.

When the search unit and reference tube or pipe had been properly located with respect to each other, the reference tube was rotated and driven longitudinally past the search unit. Controls of the ultrasonic instrument were adjusted to display a clear response from both inside and outside notches on an oscilloscope screen. The controls of the flaw-alarm module of the instrument were adjusted to position the gate properly to include the signals from the notches and to activate the alarm when they were detected. The pulse-repetition rate of the instrument was adjusted high enough to ensure the detection of all notable flaws at the speed of inspection.

The inspection speed was controlled by the rate of rotation and longitudinal movement per revolution (pitch) of the tube. The allowable pitch was a function of the length of the line-focused ultrasonic beam and the size of the flaw to be detected. Normally, when the reference standard was passed through the unit, the controls had been adjusted to provide more than one signal from each of the notches. When this had been established, the system was properly calibrated for production inspection.

Ultrasonic Inspection Precautions. Generally, a chart recorder is employed to provide a permanent record of the inspection described in Example 2. Multiple search units can be used in the immersion tank to provide several simultaneous inspections during one pass of the pipe or tube through the unit. Specifications may call for circumferential inspection from two directions because the reflection from a flaw may vary, depending on the direction in which the ultrasonic beam strikes it. In addition to the circumferential inspection to detect longitudinal flaws, a longitudinal (axial) inspection may be required to detect transverse flaws. Also, it may be desirable to ultrasonically measure wall thickness, eccentricity, or both. All these tests can be performed at the same time by utilizing search units that are designed for the tests and that are properly positioned in the tank.

Normally, rejection is based on the presence of flaw indications exceeding those from the reference notch. Reworking and reinspection are generally permitted if other requirements, such as minimum wall thickness, are satisfied.

Other refinements are included in, or can be added to, the inspection system. For example, the feeding of tubes to the unit and their withdrawal can be automated. Various audible and visible alarm systems and marking devices can be added.

Normally, the water used in the system is filtered and deaerated. Air entrapped in the water can produce false indications. Similarly, water on the inside surfaces of tubes will produce false signals, and these surfaces must be kept dry. Tubes are connected to each other by stoppers or by taping the ends together. The glands at each end of the water tank must be cut in a manner that will allow passage of the tubes without undue loss of water couplant. Finally, air must be prevented from being drawn into the entry gland along with the tube. This is usually accomplished by directing a stream of water over the outside of the tube just before it enters the gland.

In eddy current inspection, use of an encircling detector coil is limited to a maximum tube diameter of about 75 mm (3 in.). As tube diameter increases, the ratio of flaw size to tube diameter decreases; consequently, the flaw is increasingly more difficult to detect. This problem is overcome by using several small probe coils (Ref 6, 7, and 17) and with spinning probes (Ref 8). When probe coils are used, the flaw becomes a significantly high percentage of the zone surveyed. Because independently mounted probes ride over the tube surface, good magnetic coupling is ensured. Magnetic saturation is used to obtain maximum sensitivity to flaws close to, or on, the inside surface of the tube, and the frequency

of the test current is kept relatively low, sometimes as low as 1 kHz. Internal spinning probes can also be used if a lower production rate can be tolerated (Ref 8).

In some installations, the eddy current test with magnetic saturation is supplemented by a probe-type eddy current test, which in effect provides high-sensitivity inspection of the surface (Ref 18). Four probe coils, as shown in Fig. 7, each serving as both inductor and detector, rotate about the tube as it moves longitudinally through the rotating assembly. Magnetic saturation is not required. The segment of the tube in which the flaw occurs is identified by markers. In Fig. 8, the test head is shown ready for use, with eight paint-spray guns in position for marking the proper zone.

Fig. 7 Unit used for the probe-type eddy current inspection of seamless steel tubing. A, outer cover, containing test head (Fig. 8), in open position; B, one of four rotating eddy current probe coils; C, reference-standard testpiece in position for calibration; D, one of eight paint-spray guns for marking

Fig. 8 Test head of the eddy current inspection unit shown in Fig. 7. A, orifice for test pipe or tube; B, one of eight paint-spray guns for marking; C, reference-standard testpiece

Eddy current inspection is used on seamless tubular products ranging from 3.2 to 244 mm ($\frac{1}{8}$ to $9\frac{5}{8}$ in.) in diameter and from 0.25 to 14.0 mm (0.01 to 0.55 in.) in wall thickness. In most cases, magnetic saturation is used, but when the primary concern is the detection of surface imperfections, small probe coils without magnetic saturation are used. If the steel is entirely nonmagnetic, no saturation is required in any system. The frequency used ranges from 1 to 400 kHz and depends on such variables as the wall thickness of the pipe or tube, the coil design and arrangement, and the use of saturation. The spacing between the pipe or tube and the test coil(s) varies widely. However, for high sensitivity and accuracy, it should be kept to a minimum and is occasionally kept to as little as 0.25 mm (0.01 in.). This clearance is insufficient for practical use, and the usual clearance for production testing ranges from 1.6 to 19 mm ($\frac{1}{16}$ to $\frac{3}{4}$ in.).

Although all flaws that usually occur in seamless pipe or tube can be detected by eddy current methods, external flaws are more easily detected than internal flaws. Laminations are the most difficult flaws to detect. Some installations are intended to detect surface flaws only.

Flux leakage techniques are used for the inspection of seamless tubular products ranging from 32 to 914 mm ($1\frac{1}{4}$ to 36 in.) in diameter and from 3.2 to 19 mm ($\frac{1}{8}$ to $\frac{3}{4}$ in.) in wall thickness. Because the flaws sought usually have a significant longitudinal dimension, transverse magnetic fields are usually used. Longitudinal fields can be used but are rarely considered necessary. As a rule, the transverse magnetic field is produced by a current passing through a conductor located in the center of the pipe or tube. In some cases, the field is produced between the poles of an electromagnet or a permanent magnet whose pole pieces are shaped to fit the pipe or tube diameters. The signal-generating movement of either the tube or the probe with respect to the other is accomplished by rotating either tube or probe.

Sensitivity to inside surface flaws is a problem when using these methods; the problem becomes more serious as the wall thickness increases. In some cases, the solution to the problem is a rotating internal probe moving through the tube or kept stationary while the tube moves (Ref 8). Other installations depend on electronic filters and the difference in frequency between the signals for internal and surface flaws (Ref 10).

The production rate of flux leakage inspection depends on many factors. The maximum permissible speed of probe or tube movement with respect to the other is about 90 m/min (300 sfm). The circuits will respond almost instantaneously when inspection speeds are kept below this speed limit. The principal limiting factor in production-output speed then becomes the maximum tolerable length of the flaw, which in turn governs the pitch of the helix inspected. However, the production rate can be increased to any desired level by the simultaneous inspection of several segments of the same pipe or tube. Actual inspection speeds range from 0.9 to 60 m/min (3 to 200 sfm), depending on the diameter, the system used, sensitivity required, and other variables. The methods that use external magnets can inspect at a much higher overall rate than those that depend on an internal conductor for magnetization.

Magnetic particle and liquid penetrant inspection methods are simple and economical and are most useful for surface inspection in specialized, small-scale applications. When applied to welded tubing, their use can be restricted to the weld zone. However, when applied to seamless tubing, there are no surface restrictions. The inability of these methods to locate small flaws beneath the surface and their dependence on the vision, alertness, and judgment of the inspector limit their usefulness in meeting modern specifications for seamless steel tubing.

Radiographic Inspection. The principal application of radiography to seamless tubing, as with welded tubing, is the inspection of girth welds joining the ends of tubes. Even in this application, it is apparent that it should be supplemented by magnetic particle inspection (Ref 12).

Nondestructive Inspection of Tubular Products

Finned Tubing

The production of finned tubing for use in heat exchangers, notably, the heat exchangers used in nuclear reactor installations, has been increasing. These tubes are normally designed with three or six fins, and the presence of these fins precludes the use of several of the conventional inspection techniques. Among the methods considered to be feasible are the magnetic particle, liquid penetrant, and eddy current methods. The tube wall just below the outer surface can be inspected with a high degree of efficiency and speed using special eddy current techniques (Ref 19). For this application, external coils are designed to fit the external tube contours precisely. The transmission method, in which the exiting and receiving coils are placed on different sides of the tube wall, is used. Although ultrasonic inspection can be used, it is prohibitively slow and expensive because of the finned-tube contours.

Duplex Tubing

Exploratory tests have demonstrated the feasibility of applying several nondestructive inspection methods to the inspection of duplex tubing used in the atomic energy industry. The tubes, which are made by metallurgically bonding two concentric pieces of 2.25Cr-1Mo steel tubing to make a single piece, have a composite wall thickness of 3.86 mm (0.152 in.) and an outside diameter of 22 mm ($\frac{7}{8}$ in.). The outer 22 mm ($\frac{7}{8}$ in.) diam tube is fabricated with four equally spaced axial grooves on the inside surface. These grooves complicate testing, but laboratory experience indicates that a useful inspection of the assembled tubes can be accomplished by the ultrasonic method (Ref 20). Complete inspection requires scanning of the inside 14.5 mm ($\frac{9}{16}$ in.) diam tube as well as the outer tube surfaces. Eddy current techniques can also be used for inspecting duplex tubing, as will be shown in the next section, "Nonferrous Tubing," which includes an example of the eddy current inspection of aluminum tubing (Example 3).

Nondestructive Inspection of Tubular Products

Nonferrous Tubing*

A wide variety of nonferrous alloy tubing, such as tubing made of brass, copper, aluminum, nickel, and zirconium, can be inspected for cracks, seams, splits, and other flaws. Eddy current inspection is the method most widely used, followed by the ultrasonic and liquid penetrant methods.

Eddy Current Inspection

When eddy current inspection is employed for nonferrous tubing, the range of tube diameters normally permits the use of an encircling coil. The typical flaws respond well to differential-type coils. The frequencies employed usually range from 1 to 25 kHz. The choice of frequency is generally dependent on the electrical conductivity and wall thickness of the tubing. Because magnetic saturation is not required, the inspection equipment is simpler and more compact than that used on ferromagnetic tubing. Tubes range from 3.2 to 89 mm ($\frac{1}{8}$ to $3\frac{1}{2}$ in.) in diameter, with wall thicknesses from 0.25 to 14.2 mm (0.01 to 0.56 in.). Testing speeds to 370 m/min (1200 sfm) have been reported. On a limited basis, eddy current inspection is also being applied to finned copper tubing.

Example 3: Corrosion of Duplex 3003-H14 Aluminum Heat Exchanger Tubes Clad With 7072 Aluminum on Inner Surface.

An eddy current inspection was performed at a petrochemical complex on a heat exchanger containing 1319 tubes. It was advised that the tube material was aluminum alloy 3003 in the H14 condition. The tube side environment was salt water at a pressure of 240 kPa (35 psig) at an inlet temperature of 30 °C (85 °F) and an outlet temperature of 40 °C (100 °F). The shell side environment contained hydrocarbons, hydrogen sulfide, water, hydrogen, and ammonia. The shell side stream entered at 125 °C (260 °F) and exited at 45 °C (110 °F) at 380 kPa (55 psig).

Eddy current inspection of the heat exchanger revealed that 300 out of 1319 tubes exhibited indications characteristic of broad, inner-surface pitting corrosion. The suspect tubes were randomly scattered about the tube bundle.

A tube that exhibited strong indications of inner-surface pitting was pulled, split, and visually examined. The entire outer surface of the tube was covered with a thin, uniform black scale. The inner surface of the tube was coated with light-brown silt deposits. Broad, shallow corrosion pits were randomly scattered over the entire inner surface. Without exception, at each of the corroded areas, the depth of the corrosion attack measured 0.28 mm (0.011 in.). Figure 9(a) shows the outer and inner surfaces of the subject tube.

Fig. 9 Corrosion in duplex 3003-H14 aluminum heat exchanger tubes clad with 7072 aluminum on inner surface. (a) Macrograph showing aluminum tube samples removed from the subject heat exchanger unit after eddy current inspection. The outer surface of the tube is shown at the top. The center two sections illustrate the condition of the inner surface before cleaning, and the bottom section shows the inner surface after removal of the light silt deposits. Broad patches of corrosion attack are evident on the inner surface. (b) Micrograph of the inner surface of the duplex tube showing corrosion of the 7072 cladding (top section of photograph). The corrosive attack was limited to the clad thickness (0.28 mm, or 0.011 in.), and the substrate 3003 alloy was not affected. 50 \times . Courtesy of J.P. Crosson, Lucius Pitkin, Inc.

Metallographic examination revealed the tube to be of duplex design; that is, it was clad on the inner surface. The corrosive attack was limited to the cladding thickness of 0.28 mm (0.011 in.) as shown in Fig. 9(b). Qualitative spectrographic analysis revealed the aluminum alloy 3003 tube material to be clad on the inner surface with aluminum alloy 7072.

The examination revealed that the subject tubes had undergone galvanic corrosion. The 7072 cladding sacrificially corroded as it electrochemically protected the substrate alloy; 7072 cladding alloy is sufficiently anodic in the tube side environment to provide cathodic protection. Consequently, the corrosive attack penetrated only to the interface, then proceeded laterally along the substrate surface, confined to the cladding. To the extent that the cladding remained over a sufficient area, the substrate material was protected. Therefore, although the tubes exhibited corrosive attack, it was apparent that considerable service life remained, and tube replacement was not recommended.

Example 4: Stress-Corrosion Cracking of Copper Absorber Tubes in an Air-Conditioning Unit.

Eddy current inspection was performed on a leaking absorber bundle in an absorption air-conditioning unit. The inspection revealed cracklike indications in approximately 50% of the tubes. The tube material was phosphorus-deoxidized copper.

Two tubes with indications were pulled and examined visually and metallographically to determine the cause of cracking. The outer surfaces of the tubes were irregularly stained with a green-blue-black film, apparently the result of reaction with the shell side lithium bromide solution. The inner surfaces were covered with a thin, crusty green-black deposit that easily flaked off from the surface. No significant corrosive attack was observed on the inner surfaces.

One of the pulled tubes exhibited a large, irregular longitudinal crack, as shown in Fig. 10(a). The other tube exhibited a very fine longitudinal crack, as shown in Fig. 10(b).

Fig. 10 Longitudinal crack and intergranular stress-corrosion cracks in copper air-conditioning absorber tubes. (a) Longitudinal crack in one of the subject absorber tubes. 0.75 \times . (b) Macrograph of fine, irregular crack observed on the outer surface of the second absorber tube after light acid cleaning to remove the corrosion product. 2 \times . (c) Micrograph showing profiles of the primary crack and two fine secondary cracks at the outer surface of the subject absorber tube. The crack profiles are typical of stress-corrosion cracking, that is, intergranular and free of any localized grain deformation. 75 \times . Courtesy of J.P. Crosson, Lucius Pitkin, Inc.

Metallographic examination revealed that the cracks originated at the outer surface, were intergranular in nature, and were free of any localized grain deformation. Such features are characteristic of stress-corrosion cracking in a copper heat exchanger tube. The crack path is shown in Fig. 10(c).

The service contractor responsible for maintaining the absorption unit suspected that mercury contamination from a manometer was the cause of the stress-corrosion cracking. However, an electron probe microanalysis performed on a microspecimen did not reveal any mercury at or near the cracks.

Chemical analysis of the lithium bromide solution revealed significant quantities of nitrates in the solution. Such nitrates are normally added to the lithium bromide solution to act as corrosion inhibitors.

The results of the examination indicated that the absorber tubes failed by stress-corrosion cracking initiated by ammonia contamination in the lithium bromide solution. Cracking was from the shell side or outer surface of the tubes, where the tubes were in contact with nitrate-inhibited lithium bromide. The source of ammonia was apparently the reduction of nitrates by hydrogen evolved during corrosion of the steel shell and/or tubes.

Example 5: Burst Copper Evaporator Tubes in an Absorption Air-Conditioning Unit.

An eddy current survey of the copper evaporator (chiller) tubes in an absorption air-conditioning unit revealed two tubes in the evaporator bundle with indications typical of longitudinal cracks. The two tubes were pulled for visual and metallographic examination.

One tube exhibited a 27 mm ($1\frac{1}{16}$ in.) long longitudinal crack adjacent to the location of the first tube support. The second tube exhibited a 14.5 mm ($\frac{9}{16}$ in.) long longitudinal crack 1735 mm ($68\frac{1}{4}$ in.) from the front end. The tube surface adjacent to the cracks appeared to be bulged and smeared. The smearing was apparently a result of removing the tubes from the unit.

Splitting the tubes revealed the inner surfaces to exhibit a thin, normal, uniform oxide scale. The tube wall beneath the scale was free of any significant corrosion.

Metallographic examination revealed significant necking down and grain distortion at the fracture surfaces, as shown in Fig. 11. The fracture features were characteristic of an overload failure in a ductile material. The general microstructure away from the fracture consisted of twinned equiaxed grains typical of annealed copper and was considered satisfactory.

Fig. 11 Micrograph of a transverse section of a burst copper evaporator tube showing the longitudinal rupture present in one of the failed tubes. At the fracture, grain deformation and necking down of the tube wall are evident. Such features are characteristic of overload failure in a ductile material. 55×. Courtesy of J.P. Crosson, Lucius Pitkin, Inc.

The results of the examination indicated that the ruptured tubes failed as a result of excessive internal pressure, as evidenced by the necking down of the tube wall at the fracture. The normal operating pressure of approximately 690 kPa (100 psi) produces a hoop stress in the tube wall of approximately 7.6 MPa (1100 psi), which was well below the yield strength of the material. Therefore, the failure could not be related to minor fluctuations in operation pressure. The source of the excessive internal pressure was most probably a freeze-up of the tube side water that occurred during interruption of the tube side flow or misoperation of the unit.

Example 6: Worn Copper Condenser and Chiller Tubes in a Centrifugal Air-Conditioning Unit.

Eddy current inspection was performed on the copper chiller and condenser tubes of a centrifugal air-conditioning unit. The results of this inspection revealed the presence of seven chiller tubes exhibiting indications characteristic of a decrease in wall thickness at a location corresponding to the forward tube support plate. Subsequent removal of these tubes confirmed the presence of tube-wall wear at the saddle (smooth portion) of the tube, which sits in the tube support. The tube-wall wear at the support saddles was measured between 10 and 60% of the original wall thickness.

Two condenser tubes were also observed with wear at the support saddles. The decrease in wall thickness was measured to be 20% and 50% for the two tubes. Figure 12 shows several tubes with tube-wall wear at the tube support saddles. Results of the inspection attributed the wear to fretting corrosion attack caused by vibrational contact between the tubes and the steel tube support plate.

Fig. 12 Grooves at the tube support saddles formed by fretting corrosion attack due to vibrational contact between the copper tubes and the steel tube support plates. Courtesy of J.P. Crosson, Lucius Pitkin, Inc.

Immersion ultrasonic inspection is used on tubes ranging in diameter from 6.4 to 254 mm ($\frac{1}{4}$ to 10 in.), with wall thicknesses as small as 0.25 mm (0.01 in.). In some installations, four channels are used, two for the detection of transverse flaws and two for longitudinal flaws. Because these tests are usually critical, they are performed at low speeds, usually less than 3 m/min (10 sfm).

The liquid penetrant inspection of nonferrous tubular products is performed in the conventional manner, as described in the article "Liquid Penetrant Inspection" in this Volume.

Nondestructive Inspection of Tubular Products

In-Service Inspection **

The demand for the in-service inspection of tubular products has been increasing in many industries, including the petroleum, chemical, nuclear, and steelmaking industries. When there is access to the outer surface of the tubing, several of the conventional inspection methods can be used, but when the outside surface is inaccessible, the problem is more complex because the test equipment must pass through the tube. This requirement sharply limits the inspection methods and equipment that can be used.

Tubular Products in Commercial Applications

Equipment used to inspect from the inside surface must use transducers that move with respect to the shape of the testpiece being inspected. Even with this limitation, the variety of eddy current, flux leakage, and ultrasonic devices available is large enough that commercial equipment can usually be found that is capable of meeting all requirements.

Both eddy current equipment and flux leakage equipment have been successful in applications that require passage through the tube. In one application employing eddy current equipment, a combination exciting and detector probe is rotated as it passes through the tube of a reactor heat exchanger. The equipment has high sensitivity and operates at high speed (Ref 19). If the tubes are made of a nominally nonmagnetic metal that is slightly and variably magnetic, such as a Monel alloy or an austenitic stainless steel, it is necessary to magnetically saturate the tubes, using either a direct current field or a permanent magnet. A combination of the three units--inductor, detector, and saturator--built into a small probe has been successfully used to detect small flaws in the 13 mm ($\frac{1}{2}$ in.) diam by 1.24 mm (0.049 in.) wall tubes of a nuclear power plant steam generator (Ref 21).

Acoustic emission is a promising technique for the nondestructive inspection of buried pipe. Holes are drilled through the soil to the pipe at intervals of perhaps 120 m (400 ft) to allow sensors to be placed on the pipe. A heavy truck, driven over the area in which the pipe is buried, produces simultaneous indications on the instrumentation connected to each sensor. Analysis of the indication determines the presence or absence of cracks. Examples 7, 8, 9, 10 show typical uses of the ultrasonic inspection and eddy current inspection of tubular products.

Example 7: Intergranular Attack and Root Cracks in Welded Austenitic Stainless Steel Tubing Detected Using Contact Shear-Wave Ultrasound Techniques.

Contact shear-wave inspection techniques are very effective for detecting intergranular attack and/or root weld cracking in stainless steel tubing. These techniques were developed to overcome the limitations of inspecting formed and installed tubing in aircraft or other areas having limited accessibility.

This example demonstrates techniques applied to 9.5 mm ($\frac{3}{8}$ in.) outside diameter stainless steel tubing with a 0.51 mm (0.020 in.) wall thickness. However, these techniques can be modified to enable detection of intergranular attack and/or root weld cracking in various materials and sizes.

A 15-MHz Rayleigh (surface) wave transducer is machined with a 4.8 mm ($\frac{3}{16}$ in.) radius to fit the 9.5 mm ($\frac{3}{8}$ in.) outside diameter of the 0.51 mm (0.020 in.) wall thickness tubing to be inspected (Fig. 13a). The transducer is then positioned on the tubing, as shown in Fig. 13(b). No prior preparation of the sample was required. Mixed-mode shear wave is induced in the tubing to detect intergranular attack (Fig. 14) using a ring-pattern CRT display (Fig. 15). This transducer is also very sensitive and can be used for detecting root weld cracks (Fig. 16). The ultrasound instrument will be set up for monitoring discrete echoes from the root crack. The display produced is shown in Fig. 17.

Example 8: Eddy Current Inspection of Pitting and Stress-Corrosion Cracking of Type 316 Stainless Steel Evaporator Tubes in a Chemical Processing Operation.

Eddy current inspection was performed on a vertical evaporator unit used in a chemical processing plant. The evaporator contained 180 tubes 25 mm (1 in.) in diameter.

It was advised that the tube material was type 316 stainless steel. The shell side fluid was condensate and gaseous methylene chloride, while the tube side fluid was contaminated liquid methylene chloride.

Eddy current inspection revealed 101 tubes that exhibited severe outer surface pitting and cracklike indications near each tube sheet. Several tubes exhibiting strong indications were pulled and examined visually and metallurgically.

It was observed that the indications correlated with rust-stained, pitted, and cracked areas on the outer surfaces. The observed condition was most severe along the portions of the tubes located between the upper tube support and top tube sheet. Figures 18(a) and 18(b) show a pitted and cracked area before and after dye-penetration application.

Fig. 18 Pitting and stress corrosion in type 316 stainless steel evaporator tubes. (a) Rust-stained and pitted area near the top of the evaporator tube. Not clear in the photograph, but visually discernible, are myriads of fine, irregular cracks. (b) Same area shown in (a) but after dye-penetrant application to delineate the extensive fine cracks associated with the rust-stained, pitted surface. (c) Numerous multibranched, transgranular stress-corrosion cracks initiating from the outer surface pits. 35×. Courtesy of J.P. Crosson, Lucius Pitkin, Inc.

Metallographic examination revealed that the cracking initiated from the outer surface, frequently at pits, and penetrated the tube wall in a transgranular, branching fashion. The crack features were characteristic of chloride stress-corrosion

cracking. In many cases, the cracking, rather than penetrating straight through the tube wall, veered off in a tangential direction at or about mid-wall, suggesting the possibility of a change in the residual stress-field from tube drawing. Figure 18(c) shows stress-corrosion cracking originating from pits on the outer surface of the tube.

The results of the examination indicated that the subject tube failures occurred by way of stress-corrosion cracking as a result of exposure to a wet-chloride-containing environment. Therefore, a change in tube material was recommended to avoid future failures and loss of service.

Example 9: Eddy Current Inspection of a Pitted Type 316 Stainless Steel Condenser Tube.

Eddy current inspection was performed on approximately 200 stainless steel tubes in a main condenser unit aboard a container ship. The stainless steel tubes comprised the upper two tube rows in the condenser. The tube material was reported to be type 316 stainless steel; this was confirmed by subsequent chemical analysis. The remaining tubes were 90Cu-10Ni. Recurring leaks had occurred in the stainless steel tubes, but no leaks had occurred in the copper-nickel tubes.

Eddy current indications typical of inner surface pitting were observed in 75% of the stainless steel tubes inspected. A tube exhibiting a strong indication was pulled from the condenser and examined visually and metallographically.

Visual examination of the outer surface revealed occasional patches of rust-colored deposit at the locations of the eddy current indications. No apparent defects of any type were observed on the outer surface.

Subsequent splitting of the tube revealed several areas of severe pitting corrosion attack on the inner surface at locations corresponding to the eddy current indications. The corrosion progressed in such a way as to hollow out the wall thickness, and at several locations the pits had completely penetrated the wall thickness. The pitting corrosion attack tended to be close to the bottom of the tube and essentially in line along the tube sample length.

Figure 19(a) shows a severely pitted location. Metallographic examination revealed the attack to be broad and transgranular in nature without any corrosion product build-up at or around the pits. Figure 19(b) shows the manner in which the pitting had penetrated into and beneath the inner surface.

Fig. 19 Pitted type 316 stainless steel condenser tube. (a) Inner surface of main condenser tube showing extensive but localized pitting corrosion attack. 1×. (b) Longitudinal section passing through a pitted area showing extensive pitting that had progressed beneath the inner surface of the main condenser tube. 55×. Courtesy of J.P. Crosson, Lucius Pitkin, Inc.

The results of the examination revealed that the subject stainless steel condenser tube had failed as a result of pitting corrosion attack, which initiated at the inner surface and progressed through the tube wall. That the pitting was essentially on the bottom of the tubes was strong evidence of deposit-type pitting corrosion attack.

Deposit attack occurs when foreign material carried by the tube side fluid settles or deposits on the inner surface, generally at the bottom of the tube. The deposit shields the tube surface, creating a stagnant condition in which the fluid beneath the deposit becomes deficient in oxygen compared to the free-flowing fluid around the deposit. The difference in

oxygen content results in the formation of an oxygen concentration cell in which the smaller, oxygen-deficient sites become anodic with respect to the larger oxygenated cathodic sites. As a result, pitting corrosion attack occurs at the anodic sites.

In stainless steel, the condition is further aggravated by the fact that type 316 stainless steel performs best in a service where the fluid is oxidizing and forms a passive film on the surface of the tube. If there is an interruption in the film, as may be caused by chemical breakdown through decomposition of organic materials or mechanically by abrasion, and if the damage film is not reformed, pitting corrosion will initiate and grow at the damaged site. In main condenser service, certain deposits, such as shells, sand, or decomposing sea life, can initiate breakdown of the passive film.

Example 10: Eddy Current Inspection of a Magnetic Deposit Located on a Steel Tube at Tube Sheet Joint in a Centrifugal Air-Conditioning Unit.

In this case, defective tubes were not detected. However, the results of the eddy current inspection were directly influenced by a previous tube failure in the unit.

Eddy current inspection of the condenser bundle of a centrifugal air-conditioning unit revealed several tubes with indications typical of tube-wall wear at locations corresponding to the tube supports. One of the tubes exhibiting indications was pulled and visually examined. A tightly adherent magnetic deposit was observed at the area of the tube in contact with the first tube support. Splitting the tube revealed the deposit to be tightly packed in the fins, as shown in Fig. 20. This tube was of tru-finned rather than skip-finned design; that is, the tube did not have smooth support saddles where it was in contact with the tube support plate. Instead, the tube was finned from end to end. Therefore, although the test instrument parameters were selected to phase out the magnetically induced indications from the steel tube supports, the magnetic deposit, which was tightly embedded between the fins, was closer to the internal test probe and caused an indication that was interpreted as tube-wall wear.

Fig. 20 Magnetic corrosion product embedded in the tube fins at the tube support of a steel tube. The corrosion product caused by eddy current indication characteristic of tube-wall wear at the support. Courtesy of J.P. Crosson, Lucius Pitkin, Inc.

Through further investigation it was determined that a previous tube failure had caused the Freon on the shell side to become contaminated with water. This condition proved corrosive to the steel supports and shell and subsequently caused the magnetic corrosion deposit observed at the tube support.

Oil-Country Tubular Products

The application of nondestructive inspection to the tubular products of the oil and gas distribution industry is extensive and is vital to successful operation. The American Petroleum Institute has, with international cooperation and international acceptance, developed tubing and pipe specifications that include many rigorous requirements for nondestructive inspection (Ref 22). Inspection installations range from simple magnetic particle installations to complex assemblies of machinery whose continuous productivity is completely dependent on the reliability and accuracy of its nondestructive inspection equipment. The larger installations may use ultrasonic, eddy current, flux leakage, or radiographic equipment, singly or in combination, and can be supplemented by magnetic particle inspection.

The inspections of pipe or casing can be performed during manufacture, when it is received on site, while it is in service, or when it must be inspected for reuse or resale. When inspection is included in the manufacturing operation, tests are usually performed immediately after the pipe is produced and again after processing has been completed.

Industry has promoted the development and use of highly sophisticated equipment for the in-service inspection of pipe in diameters of 75 mm (3 in.) and larger. In one of several different pipe crawlers available commercially, the probe travels through the gas lines and, by means of flux leakage measurements, reports on the condition of the pipe. Another type of in-service inspection unit, which is shown in Fig. 21, includes tight-fitting seals so that it can be propelled through the pipelines by the oil or gas being carried. The traveling unit includes not only the test instrumentation and a tape recorder but also a power supply so that it is completely self-sufficient, requiring no connection outside the pipe. The sections of this unit are connected by universal joints to permit passage around bends. When the unit completes its cycle, total information on the condition of the pipe is immediately available.

Fig. 21 Self-contained flux leakage inspection unit used in oil and gas pipeline for in-service inspection

One of the most important inspection procedures in this industry involves the inspection of girth welds joining the ends of pipes to each other or to fittings and bends. Although radiographic tests are widely favored for this application (Ref 23), supplementary tests are needed to detect the tightly closed flaws not detected by radiography (Ref 12). This industry also uses automated inspection of small tubular pipe couplings. One machine separates acceptable couplings from rejectable couplings automatically and requires no operator. The couplings are fed into the machine from a cutoff lathe. After automatic inspection to API specifications, rejectable couplings are diverted to a reject receptacle.

Nondestructive Inspection of Steel Pipelines (Ref 24)

The nondestructive inspection of welds in steel pipe is used to eliminate discontinuities that could cause failure or leakage. Most steel pipes for gas transmission are made by the hot rotary forging of pierced billets or by forming plate or strip and then welding by either the submerged arc or the resistance process. Pipes are usually made to one of the API specifications, with supplementary requirements if necessary.

Submerged Arc Welded Pipe. The shrinkage of liquid metal upon solidification results in primary piping in the ingot, which can cause laminations oriented in the plane of the plate or strip rolled from the ingot. Laminations can also result from secondary piping and from large inclusions. Laminations can nucleate discontinuities during welding or propagate to form a split in the weld. They cannot be detected by radiography, because of their orientation, but they can be detected by ultrasonics or can be seen when they occur as skin laminations.

The API specifications do not require nondestructive inspection of the plate or strip before welding, but ultrasonic inspection is mandatory in some customer requirements. Generally, the periphery of the plates must be examined to ensure that edges to be welded are free of laminations.

Pulse-echo ultrasonic inspection has been used for most plate-inspection specifications. This method cannot distinguish laminations near the surface remote from the probe, because the echoes from the laminations cannot be inspected from the back echo. Some specifications require that the plate be inspected from both surfaces or that transmission methods be used.

Manual scanning, although time consuming, is feasible because the echo pattern from laminations persists on the oscilloscope screen and is easy to interpret. However, if laminations are fragmented or at an oblique angle to the surface of the plate, there is no distinct flaw echo, but merely a loss of back echo. In most pulse-echo equipment, no account is taken of this loss; therefore, transmission methods are preferable for plate inspection. Such methods normally require mechanization with automatic recording of the results, and inspection systems based on these methods have been installed in some plate mills.

In both transmission and pulse-echo inspection, the probe area represents the area of the plate under inspection at any instant. Shear-wave angle probes are used to detect lamination, but the method is not reliable, particularly for the thin plates used in pipe manufacture. Laminations can also be detected by ultrasonic Lamb waves, which can inspect a zone extending across some or all of the plate. Lamb waves have been used on steel sheet, but they cannot be excited in plates more than 6.4 mm ($\frac{1}{4}$ in.) thick using standard equipment. Special equipment is now available for plate up to 13 mm ($\frac{1}{2}$ in.) thick.

The main flaws that occur in submerged arc welds are incomplete fusion and incomplete penetration between the inside and outside weld beads or between the base metal and the filler metal, cracks, undercut or underfill, and overflow. The API standards require full-length inspection of welds by radiography or ultrasonics. Fluorescent screens or television screens are permitted for radiography, and they are often used because they are less expensive than radiographic film, although less discriminating. Fluoroscopy is inherently less sensitive to the more critical flaws, cracks, incomplete sidewall fusion, and incomplete penetration. Ultrasonic inspection is more sensitive to serious flaws and can be automated.

The arrangements of transmitter and receiver probes in ultrasonic inspection of submerged arc welded pipe for detection of longitudinally and transversely oriented discontinuities are shown in Fig. 22. The region of the oscilloscope time base corresponding to the weld region is analyzed electronically, and echoes above the amplitude of the reference derived from the calibration block actuate a relay that can operate visible or audible warnings, paint sprays, or pen recorders. In some installations, only one probe is used on each side of the weld, and detection of discontinuities that are oriented transversely to the weld is not possible. To ensure correct lateral positioning of the probes on the weld, they are mounted on a frame, which is then moved along the weld; alternatively, the pipe can be moved past stationary probes.

Fig. 22 Diagram of arrangements of probes in the ultrasonic inspection of submerged arc welded pipe for the detection of (a) longitudinally oriented and (b) transversely oriented discontinuities

Accurate positioning of the probes over the welds is difficult because the width, shape, and straightness of the weld bead vary. The inspection area is limited in order to reduce confusion between echoes from flaws within the weld and the boundaries of the weld reinforcement. Acoustic coupling can be reduced by the probes riding up on weld spatter, by drifting of the scanning frame, by loss of coupling water, or by loose mill scale.

General practice is to use automatic ultrasonic inspection methods and to radiograph those regions of the pipe suspected of containing discontinuities. If radiography does not reveal an objectionable flaw, the ultrasonic indication is ignored and the pipe is accepted. This procedure would accept cracks or laminations parallel to the plate surface that, because of their orientation, cannot be detected by radiography. As an alternative approach, regions that give an ultrasonic flaw indication should be inspected radiographically and by manual ultrasonics. If the original ultrasonic indication was from a discontinuity shown by the radiograph to be acceptable within the specification or if the manual ultrasonic inspection revealed that the indication was a spurious echo arising from a surface wave or from local weld shape, then the pipe was accepted; if the radiograph showed an objectionable flaw, then the pipe was rejected. If there was no explanation for the echo, it was assumed to have arisen from a discontinuity adversely oriented for radiography.

Seamless Pipe. There are two sources of flaws in roll forged seamless pipe: inhomogeneities and the manufacturing process. Inhomogeneities in the ingot such as primary and secondary ingot pipe can be carried into the roll-forged product and can cause flaws in a similar manner to the formation of laminations in steel plate. Such flaws are likely to have a

major dimension oriented in the plane of the pipe wall. In manufacturing, the rolls and the mandrel can cause surface discontinuities such as tears and laps, and such discontinuities will have substantial orientation normal to the pipe wall. In addition, pipes and tubes produced by working pierced billets are prone to eccentric wall thickness, with the eccentricity varying along the length of the pipe.

The API specifications that cover seamless line pipe require neither nondestructive inspection nor wall thickness measurement away from the pipe ends. In some mills, destructive inspections are carried out on samples cut from each pipe end to determine the presence of primary pipe flaws. In some API standards (casing, tubing, and drill pipe), nondestructive inspection is optional, but in other standards (high-strength casing and tubing) nondestructive inspection of the full pipe length is mandatory. Magnetic particle, ultrasonic, or eddy current inspection methods are permitted.

Magnetic particle inspection methods have little or no sensitivity to discontinuities that do not show on the surface and are likely to detect laminar discontinuities resulting from ingot piping. Although surface laps are amenable to magnetic crack detection, it would be difficult to apply the inspection method to internal-surface discontinuities.

Eddy current inspection methods can be used to inspect seamless tubing. Very rapid inspection rates are possible with the encircling-coil system. When pipe is passed through a coil fed with alternating current, the resistive and reactive components of the coil are modified; the modification depends on dimensions (and therefore indirectly on discontinuities), electrical conductivity and magnetic permeability, and the annulus between the pipe and the coil (and therefore the outside diameter of the pipe). The analysis to determine which effect is causing any modification is complex.

Eddy current methods are extensively used for the inspection of small, nonferrous tubes, but ferrous material causes complications from magnetic permeability. The initial permeability is affected by residual-stress level. Roll-forged pipe may have varying amounts of residual cold work, depending on the original soaking conditions and the time taken to complete forging. The effect can be alleviated by applying a magnetically saturated field; equipment that can produce a magnetically saturated field has been installed in steel tube mills. However, saturation becomes more difficult as pipe diameter increases.

Radiographic inspection methods, employing either x-ray or γ -ray transmission, can be used with a scintillation counter to estimate the wall thickness of pipe. The accuracy of scintillation counters depends on the size of the count for a given increment of thickness; the count increases with the time the increment is in the beam. As a result, the count, and therefore the accuracy, increases with decreasing scanning rate. When large-diameter pipes are scanned at realistic rates, eccentricity is usually averaged out.

Ultrasonic inspection methods can detect discontinuities oriented both in the plane of, and normal to, the pipe wall. Discontinuities in the plane of the wall can be detected by using a compression-wave probe scanning at normal incidence. For discontinuities normal to the wall, the beam is converted to shear wave and propagated around or along the tube. The pipe is rotated and moved longitudinally relative to the probes, thus giving a helical scan.

The reliability of mechanized scanning is a function of acoustic coupling, and optimum results are achieved with immersion coupling. The efficiency of acoustic coupling through large columns of water is lower but much more consistent than that through the thin liquid films used in contact scanning. Immersion methods also eliminate probe wear and the requirement for specially contoured probes to accommodate each pipe size.

Alternatively, immersion coupling by a column of water flowing between the probe and the pipe can be used. With this method, probe-rotation scanning is possible. Advantage can be taken of the smaller inertia of the probes to increase the scanning rate, and therefore the speed of inspection, by about an order of magnitude.

When an ultrasonic beam propagates radially through the pipe wall, the time interval between successive back echoes reflected from the bore surface is directly proportional to the wall thickness. If the first back echo is used to trigger a high-speed electronic counter whose frequency is such that it will produce a count of 100 during the time taken to receive four echoes in 25 mm (1 in.) thick plate and if a subsequent back echo is used to stop the counter, a count proportional to the wall thickness is produced. By changing the frequency of the counter oscillator, it is possible to change the thickness range inspected or to accommodate different materials. Information from the counter can be fed to a chart recorder, thus continuously recording the wall thickness. Lamination would be recorded as an abrupt localized reduction in wall thickness.

For the detection of cracks and laplike discontinuities, the display on the flaw detection oscilloscope is gated. The discontinuity can then be recorded in its position around the circumference. Chart length can be made proportional to pipe length, thus facilitating discontinuity location and extent in relation to pipe length and variation in wall thickness around and along the pipe. Alternatively, information can be monitored in a go/no-go method to provide a paint spray that identifies the locations of significant discontinuities.

Resistance-Welded Pipe. The type of discontinuity usually responsible for the failure of resistance-welded pipe is incomplete fusion, with associated oxide film. The nondestructive inspection of larger-diameter resistance-welded pipes is normally restricted to inspection of the weld region. Systems similar to those used for the inspection of submerged arc welded seams can be employed, although the arrangements for tracking the probes with respect to the weld reinforcements are not applicable. Because of problems associated with accurate weld tracking, it is necessary that small variations in weld-probe separation should only cause acceptably small variations in discontinuity detection sensitivity.

Probe angles of 60 to 65° give satisfactory results, and coverage of the weld depth is achieved by using two probes on each side of the weld. Such a system is also relevant to the ultrasonic inspection of submerged arc welded pipes.

Nondestructive Inspection of Pipeline Girth Welds

The API specifications do not require that all girth welds be inspected; the use of radiography and the extent of coverage are optional. Generally, it has been the practice to inspect 10% of the weld length. Where the integrity of a pipeline is vital, as in high-pressure gas-transmission systems, it is advisable to consider a 100% inspection, especially when inspection is not a large proportion of the total cost of the pipeline. Where operating conditions are less critical, however, it may be possible to be less critical regarding the size and type of discontinuity permissible.

Radiographic Inspection. Characteristic discontinuities in pipeline welds are slag, elongated piping in root, scattered piping and porosity, burn-throughs in the root, incomplete root penetration, incomplete sidewall fusion, and cracks, which often break the inner surface in the heat-affected zone. Except for cracks and incomplete sidewall fusion, these discontinuities are amenable to detection by radiography. Open cracks can be detected, but tighter cracks, even though favorably oriented, are detectable only by optimum practice. Some cracks may not be revealed at all.

Assuming good radiographic techniques, radiographic quality depends on the choice of conditions that control the contrast and definition of the radiograph; the detection of discontinuities improves with increasing contrast and fine definition. Contrast can be assessed in terms of the thickness sensitivity, which can be conveniently estimated by image-quality indicators.

Many factors other than good radiographic techniques influence radiographic contrast. For pipeline radiography, radiation energy is probably the most important. The absorption of radiation by steel decreases with increasing energy; the absorption coefficient at 150 kV is about three times that at 700 kV. For optimum detection of small changes in thickness, the absorption should be as high as possible so that large differences in exposure, consistent with a reasonable amount of energy being transmitted to provide a realistic overall exposure, result at the film. Gamma radiation from a ¹⁹²Ir source is approximately equivalent to x-rays generated at 700 kV and therefore will not be absorbed sufficiently to give good contrast sensitivity. For wall thicknesses typical of pipelines, x-rays generated at about 150 to 175 kV have reasonable absorption.

For the detection and correct identification of discontinuities from the radiographic image, the delineation of the shadow must be sharp. The principal sources of unsharpness in radiographic images are geometric unsharpness, resulting from the finite size of radiation sources; unsharpness in the film resulting from the kinetic energy of the radiation, grain size of the emulsion and degree of development; and unsharpness resulting from the intensifying screen. Radiographs on pipelines are generally made under less-than-satisfactory conditions; nevertheless, it should be possible to avoid vibration and other forms of relative movement of the source and film during exposure so that the total geometric unsharpness is the penumbra effect. With piping, geometric unsharpness is not large.

An important side effect of unsharpness is that when the unsharpness is greater than the width of a flaw, the contrast resulting from the flaw is reduced from its theoretical value; the greater the unsharpness, the greater the contrast reduction. For tight cracks, the contrast may be so reduced that the change in tone is below the threshold for detection.

On-site conditions may reduce the capability of radiography to detect flaws. Under some conditions, it is difficult to maintain correct developer temperature. The operator is often pressured to keep pace with the welding crews; also,

weather and working conditions may be adverse. Suitable equipment and adequate planning should overcome these problems. The more difficult problem is the repetitiveness of the procedure, which causes the operators to lose concentration and gradually to devote less attention to detail.

For most pipe sizes it is necessary to make three exposures to cover the circumference of the weld because the length of weld that can be covered in one exposure (the diagnostic film length) is limited by fade at each end of the film. Panoramic techniques have been used on some larger-diameter pipes. The source is held in a spider arrangement and positioned on the pipe axis; the films are placed around the outer surface of the pipe at the weld. In this manner, the entire weld can be radiographed in one exposure. This exposure is shorter than one of the exposures required in the double-wall, single-image technique because the radiation has to propagate through only one wall of the pipe. In practice, the radiation source can be manually positioned only inside pipes having a diameter of 762 mm (30 in.) or more; even then, conditions must be good. Crawler devices are available that are mechanically propelled through the pipe, with the exposure being operated from an external control (see the section "In-Motion Radiography" of the article "Radiographic Inspection" in this Volume).

On pipelines where the rate of welding is low and the investment on crawlers is not justified, x-ray sets can be clamped onto the outside of the pipe and radiography implemented by the double-wall, single-image technique. Gamma radiography has been favored for pipeline radiography because of its convenience and lower cost. Source containers are more compact and portable than x-ray generators and do not require a power supply.

Panoramic x-ray radiography is barely feasible without crawler devices because of the difficulty of manually maneuvering the cumbersome x-ray sets and control units inside a pipe. Because of the potential for increased use of x-ray radiography on pipelines, there has been considerable effort applied to development of x-ray crawlers.

Ultrasonic Inspection. Welds are usually ultrasonically inspected by a pulse-echo reflection technique. Before the inspection of a weld, the pipe should be checked for laminations that may divert the beam from its theoretical path.

Discontinuities can be identified most reliably by accurate positioning of the source of the discontinuity echo, preferably during scanning from more than one direction. Skilled operators may be able to gain additional information on type of discontinuity from the shape of the echo on the oscilloscope screen, but the display on battery-operated flaw detectors used in daylight is not sufficiently distinct for the technique to be employed on pipelines.

The more significant discontinuities occur in the root of the weld, where discrimination between sources of echo reflection is more difficult. Acceptable features such as full root penetration cause echoes comparable in magnitude to those from root underbead cracks or incomplete penetration. Accurate positioning of the probe with respect to the weld centerline is necessary, and it has been suggested that the required accuracy can be achieved only by marking and machining the pipe ends before welding. Positioning from the center of the weld cap is only approximate because the weld is not necessarily symmetrical about the centerline through the root. Even with the premarking, it is difficult for an operator to locate the ultrasonic probe accurately and still be in a position to view the instrument screen. Thinner-wall pipes reduce the differences in beam path and probe position for discrimination between the various features of the root. Also, the weld must be examined with the probe-to-weld distance increased to avoid confusion between echoes from the weld and those from probe noise. This increases the effect of beam spread and may lead to extraneous echoes from the cap reinforcement.

The skip distance and beam-path length vary as the wall thickness varies. Variations in wall thickness between nominally the same classes of submerged arc welded pipe range from 10 to 15%, but in seamless pipe a $\pm 10\%$ variation along the length or around the circumference at a given position along the length is common. Although it is possible to measure wall thickness accurately by ultrasonics, it is not feasible to measure wall thickness concurrently with scanning the weld. Surface roughness can cause considerable variations in beam angle. Weld spatter can reduce the effectiveness of the coupling, and also alter beam angle by lifting part of the probe off the pipe.

Ultrasonic inspection on girth welds was originally used to determine which welds to radiograph. If the radiograph did not detect anything, it was the practice on most pipelines to accept the radiographic evidence and not that from ultrasonics. Now that pipelines are being examined 100% by radiography, the role of ultrasonics has changed to that of detecting root underbead cracks that may escape detection by radiography and of providing supplementary evidence to aid in the interpretation of radiographic images of weld-root regions.

Surface Crack Detection. Root underbead cracks break the surface of the pipe in the bore and can be detected with liquid penetrant and magnetic particle inspection. The weld area can be magnetized using a yoke powered by permanent magnets. Both methods are sensitive under ideal conditions, but liquid penetrants require very clean surfaces. Magnetic particle crack detection is therefore preferred for pipeline applications. Interpretation of the indications is not a problem, except for the confusion that may arise from the tendency of sharp changes in root profile to give a slight crack indication.

Nondestructive Inspection of Weldments, Brazed Assemblies, and Soldered Joints

Introduction

THE SELECTION of a method for inspecting weldments, brazed assemblies, and soldered joints for flaws (referred to as discontinuities in welding terminology) depends on a number of variables, including the nature of the discontinuity, the accessibility of the joint, the type of materials joined, the number of joints to be inspected, the detection capabilities of the inspection method, the level of joint quality required, and economic considerations. Regardless of the method selected, established standards must be followed to obtain valid inspection results.

In general, nondestructive inspection methods (NDI) are preferred over destructive inspection methods. Sections can be trepanned from a joint to determine its integrity; however, the joint must be refilled, and there is no certainty that discontinuities would not be introduced during repair. Destructive inspection is usually impractical, because of the high cost and the inability of such methods to accurately predict the quality of those joints that were not inspected.

This article will review nondestructive methods of inspection for weldments (including diffusion-bonded joints) and brazed and soldered joints. More detailed information on the techniques discussed can be found in the Sections "Inspection Equipment and Techniques," and "Methods of Nondestructive Evaluation" in this Volume.

Acknowledgements

The contributions of the following individuals were critical in the preparation of this article: W.H. Kennedy, Canadian Welding Bureau; Robert S. Gilmore, General Electric Research and Development Center; and John M. St. John, Caterpillar, Inc. Special thanks are also due to Michael Jenemann, Product Manager, NDT Systems, E.I. Du Pont de Nemours & Company, Inc., for supplying the reference radiographs of welds shown in Fig. 18 to 37. Finally, the efforts of the ASM Committee on Weld Discontinuities and the ASM Committee on Soldering from Volume 6 of the 9th Edition of *Metals Handbook* are gratefully acknowledged; material from the aforementioned Volume was used in this article.

Weldments

Weldments made by the various welding processes may contain discontinuities that are characteristic of that process. Therefore, each process, as well as the discontinuities typical of that process, are discussed below. Explanations of welding processes, equipment and filler metals, and welding parameters for specific metals and alloys are available in *Welding, Brazing, and Soldering*, Volume 6 of the *ASM Handbook*.

Discontinuities in Arc Welds

Discontinuities may be divided into three broad classifications: design related, welding process related, and metallurgical.

Design-related discontinuities include problems with design or structural details, choice of the wrong type of weld joint for a given application, or undesirable changes in cross section. These discontinuities, which are beyond the scope of this article, are discussed in the Section "Joint Evaluation and Quality Control" in *Welding, Brazing, and Soldering*, Volume 6 of the *ASM Handbook*.

Discontinuities resulting from the welding process include:

- *Undercut*: A groove melted into the base metal adjacent to the toe or root of a weld and left unfilled by weld metal
- *Slag inclusions*: Nonmetallic solid material entrapped in weld metal or between weld metal and base metal
- *Porosity*: Cavity-type discontinuities formed by gas entrapment during solidification
- *Overlap*: The protrusion of weld metal beyond the toe, face, or root of the weld
- *Tungsten inclusions*: Particles from tungsten electrodes that result from improper gas tungsten arc welding procedures
- *Backing piece left on*: Failure to remove material placed at the root of a weld joint to support molten weld metal
- *Shrinkage voids*: Cavity-type discontinuities normally formed by shrinkage during solidification
- *Oxide inclusions*: Particles of surface oxides that have not melted and are mixed into the weld metal
- *Lack of fusion (LOF)*: A condition in which fusion is less than complete
- *Lack of penetration (LOP)*: A condition in which joint penetration is less than that specified
- *Craters*: Depressions at the termination of a weld bead or in the molten weld pool
- *Melt-through*: A condition resulting when the arc melts through the bottom of a joint welded from one side
- *Splatter*: Metal particles expelled during welding that do not form a part of the weld
- *Arc strikes (arc burns)*: Discontinuities consisting of any localized remelted metal, heat-affected metal, or change in the surface profile of any part of a weld or base metal resulting from an arc
- *Underfill*: A depression on the face of the weld or root surface extending below the surface of the adjacent base metal

Metallurgical discontinuities include:

- *Cracks*: Fracture-type discontinuities characterized by a sharp tip and high ratio of length and width to opening displacement
- *Fissures*: Small cracklike discontinuities with only a slight separation (opening displacement) of the fracture surfaces
- *Fisheye*: A discontinuity found on the fracture surface of a weld in steel that consists of a small pore or inclusion surrounded by a bright, round area

- *Segregation*: The nonuniform distribution or concentration of impurities or alloying elements that arises during the solidification of the weld
- *Lamellar tearing*: A type of cracking that occurs in the base metal or heat-affected zone (HAZ) of restrained weld joints that is the result of inadequate ductility in the through-thickness direction of steel plate

The observed occurrence of discontinuities and their relative amounts depend largely on the welding process used, the inspection method applied, the type of weld made, the joint design and fit-up obtained, the material utilized, and the working and environmental conditions. The most frequent weld discontinuities found during manufacture, ranked in order of decreasing occurrence on the basis of arc-welding processes, are:

Shielded metal arc welding (SMAW)

Slag inclusions
Porosity
LOF/LOP
Undercut

Submerged arc welding (SAW)

LOF/LOP
Slag inclusions
Porosity

Flux cored arc welding (FCAW)

Slag inclusions
Porosity
LOF/LOP

Gas metal arc welding (GMAW)

Porosity
LOF/LOP

Gas tungsten arc welding (GTAW)

Porosity

The commonly encountered inclusions--as well as cracking, the most serious of weld defects--will be discussed in this section.

Gas porosity can occur on or just below the surface of a weld. Pores are characterized by a rounded or elongated teardrop shape with or without a sharp point. Pores can be uniformly distributed throughout the weld or isolated in small groups; they can also be concentrated at the root or toe of the weld. Porosity in welds is caused by gas entrapment in the molten metal, by too much moisture on the base or filler metal, or by improper cleaning of the joint during preparation for welding.

The type of porosity within a weld is usually designated by the amount and distribution of the pores. Some of the types are classified as follows:

- *Uniformly scattered porosity*: Characterized by pores scattered uniformly throughout the weld (Fig. 1a)
- *Cluster porosity*: Characterized by clusters of pores separated by porosity-free areas (Fig. 1b)
- *Linear porosity*: Characterized by pores that are linearly distributed (Fig. 1c). Linear porosity generally occurs in the root pass and is associated with incomplete joint penetration
- *Elongated porosity*: Characterized by highly elongated pores inclined to the direction of welding. Elongated porosity occurs in a herringbone pattern (Fig. 1a)
- *Wormhole porosity*: Characterized by elongated voids with a definite worm-type shape and texture (Fig. 2)

Fig. 1 Type of gas porosity commonly found in weld metal. (a) Uniformly scattered porosity. (b) Cluster porosity. (c) Linear porosity. (d) Elongated porosity

Fig. 2 Wormhole porosity in a weld bead. Longitudinal cut. 20×

Radiography is the most widely used nondestructive method for detecting subsurface gas porosity in weldments. The radiographic image of round porosity appears as round or oval spots with smooth edges, and elongated porosity appears as oval spots with the major axis sometimes several times longer than the minor axis. The radiographic image of wormhole porosity depends largely on the orientation of the elongated cavity with respect to the incident x-ray beam. The presence of top-surface or root reinforcement affects the sensitivity of inspection, and the presence of foreign material, such as loose scale, flux, or weld spatter, may interfere with the interpretation of results.

Ultrasonic inspection is capable of detecting subsurface porosity. However, it is not extensively used for this purpose except to inspect thick sections or inaccessible areas where radiographic sensitivity is limited. Surface finish and grain size affect the validity of the inspection results.

Eddy current inspection, like ultrasonic inspection, can be used for detecting subsurface porosity. Normally, eddy current inspection is confined to use on thin-wall welded pipe and tubing because eddy currents are relatively insensitive to flaws that do not extend to the surface or into the near-surface layer.

Magnetic particle inspection and liquid penetrant inspection are not suitable for detecting subsurface gas porosity. These methods are restricted to the detection of only those pores that are open to the surface.

Slag inclusions may occur when using welding processes that employ a slag covering for shielding purposes. (With other processes, the oxide present on the metal surface before welding may also become entrapped.) Slag inclusions can be found near the surface and in the root of a weld (Fig. 3a), between weld beads in multiple-pass welds (Fig. 3b), and at the side of a weld near the root (Fig. 3c).

Fig. 3 Sections showing locations of slag inclusions in weld metal. (a) Near the surface and in the root of a single-pass weld. (b) Between weld beads in a multiple-pass weld. (c) At the side of a weld near the root

During welding, slag may spill ahead of the arc and subsequently be covered by the weld pool because of poor joint fit-up, incorrect electrode manipulation, or forward arc blow. Slag trapped in this manner is generally located near the root. Radical motions of the electrode, such as wide weaving, may also cause slag entrapment on the sides or near the top of the weld after the slag spills into a portion of the joint that has not been filled by the molten pool. Incomplete removal of the slag from the previous pass in multiple-pass welding is another common cause of entrapment. In multiple-pass welds, slag may be entrapped any number of places in the weld between passes. Slag inclusions are generally oriented along the direction of welding.

Three methods used for the detection of slag below the surface of single-pass or multiple-pass welds are magnetic particle, radiographic, and ultrasonic inspection. Depending on their size, shape, orientation, and proximity to the surface, slag inclusions can be detected by magnetic particle inspection with a dc power source, provided the material is ferromagnetic. Radiography can be used for any material, but is the most expensive of the three methods. Ultrasonic inspection can also be used for any material and is the most reliable and least expensive method. If the weld is machined to a flush contour, flaws as close as 0.8 mm ($\frac{1}{32}$ in.) to the surface can be detected with the straight-beam technique of ultrasonic inspection, provided the instrument has sufficient sensitivity and resolution. A 5- or 10-MHz dual-element transducer is normally used in this application. If the weld cannot be machined, near-surface sensitivity will be low because the initial pulse is excessively broadened by the rough, as-welded surface. Unmachined welds can be readily inspected by direct-beam and reflected-beam techniques, using an angle-beam (shear-wave) transducer.

Tungsten inclusions are particles found in the weld metal from the nonconsumable tungsten electrode used in GTAW. These inclusions are the result of:

- Exceeding the maximum current for a given electrode size or type
- Letting the tip of the electrode make contact with the molten weld pool
- Letting the filler metal come in contact with the hot tip of the electrode
- Using an excessive electrode extension
- Inadequate gas shielding or excessive wind drafts, which result in oxidation
- Using improper shielding gases such as argon-oxygen or argon-CO₂ mixtures, which are used for GMAW

Tungsten inclusions, which are not acceptable for high-quality work, can only be found by internal inspection techniques, particularly radiographic testing.

Lack of fusion and lack of penetration result from improper electrode manipulation and the use of incorrect welding conditions. Fusion refers to the degree to which the original base metal surfaces to be welded have been fused to the filler metal. On the other hand, penetration refers to the degree to which the base metal has been melted and resolidified to result in a deeper throat than was present in the joint before welding. In effect, a joint can be completely fused but have incomplete root penetration to obtain the throat size specified. Based on these definitions, LOF discontinuities are located on the sidewalls of a joint, and LOP discontinuities are located near the root (Fig. 4). With some joint configurations, such as butt joints, the two terms can be used interchangeably. The causes of LOF include excessive travel speed, bridging, excessive electrode size, insufficient current, poor joint preparation, overly acute joint angle, improper electrode manipulation, and excessive arc blow. Lack of penetration may be the result of low welding current, excessive travel speed, improper electrode manipulation, or surface contaminants such as oxide, oil, or dirt that prevent full melting of the underlying metal.

Fig. 4 Lack of fusion in (a) a single-V-groove weld and (b) double-V-groove weld. Lack of penetration in (c) a single-V-groove and (d) a double-V-groove weld

Radiographic methods may be unable to detect these discontinuities in certain cases, because of the small effect they have on x-ray absorption. As will be described later, however, lack of sidewall fusion is readily detected by radiography. Ultrasonically, both types of discontinuities often appear as severe, almost continuous, linear porosity because of the nature of the unbonded areas of the joint. Except in thin sheet or plate, these discontinuities may be too deep-lying to be detected by magnetic particle inspection.

Geometric weld discontinuities are those associated with imperfect shape or unacceptable weld contour. Undercut, underfill, overlap, excessive reinforcement, fillet shape, and melt-through, all of which were defined earlier, are included in this grouping. Geometric discontinuities are shown schematically in Fig. 5. Radiography is used most often to detect these flaws.

Fig. 5 Weld discontinuities affecting weld shape and contour. (a) Undercut and overlapping in a fillet weld. (b) Undercut and overlapping in a groove weld. (c) and (d) Underfill in groove welds

Cracks can occur in a wide variety of shapes and types and can be located in numerous positions in and around a welded joint (Fig. 6). Cracks associated with welding can be categorized according to whether they originate in the weld itself or in the base metal. Four types commonly occur in the weld metal: transverse, longitudinal, crater, and hat cracks. Base metal cracks can be divided into seven categories: transverse cracks, underbead cracks, toe cracks, root cracks, lamellar tearing, delaminations, and fusion-line cracks.

Fig. 6 Identification of cracks according to location in weld and base metal. 1, crater crack in weld metal; 2, transverse crack in weld metal; 3, transverse crack in HAZ; 4, longitudinal crack in weld metal; 5, toe crack in base metal; 6, underbead crack in base metal; 7, fusion-line crack; 8, root crack in weld metal; 9, hat cracks in weld metal

Weld metal cracks and base metal cracks that extend to the surface can be detected by liquid penetrant and magnetic particle inspection. Magnetic particle inspection can also detect subsurface cracks, depending on their size, shape, and proximity to the surface. Although the orientation of a crack with respect to the direction of the radiation beam is the dominant factor in determining the ability of radiography to detect the crack, differences in composition between the base metal and the weld metal may create shadows to hide a crack that otherwise might be visible. Ultrasonic inspection is generally effective in detecting most cracks in the weld zone.

Transverse cracks in weld metal (No. 2, Fig. 6) are formed when the predominant contraction stresses are in the direction of the weld axis. They can be hot cracks, which separate intergranularly as the result of hot shortness or localized planar shrinkage, or they can be transgranular separations produced by stresses exceeding the strength of the material. Transverse cracks lie in a plane normal to the axis of the weld and are usually open to the surface. They usually extend across the entire face of the weld and sometimes propagate into the base metal.

Transverse cracks in base metal (No. 3, Fig. 6) occur on the surface in or near the HAZ. They are the result of the high residual stresses induced by thermal cycling during welding. High hardness, excessive restraint, and the presence of hydrogen promote their formation. Such cracks propagate into the weld or beyond the HAZ into the base metal as far as is needed to relieve the residual stresses.

Underbead cracks (No. 6, Fig. 6) are similar to transverse cracks in that they form in the HAZ because of high hardness, excessive restraint, and the presence of hydrogen. Their orientation follows the contour of the HAZ.

Longitudinal cracks (No. 4, Fig. 6) may exist in three forms, depending on their positions in the weld. Check cracks are open to the surface and extend only partway through the weld. Root cracks extend from the root to some point within the weld. Full centerline cracks may extend from the root to the face of the weld metal.

Check cracks are caused either by high contraction stresses in the final passes applied to a weld joint or by a hot-cracking mechanism.

Root cracks are the most common form of longitudinal weld metal crack because of the relatively small size of the root pass. If such cracks are not removed, they can propagate through the weld as subsequent passes are applied. This is the usual mechanism by which full centerline cracks are formed.

Centerline cracks may occur at either high or low temperatures. At low temperatures, cracking is generally the result of poor fit-up, overly rigid fit-up, or a small ratio of weld metal to base metal.

All three types of longitudinal cracks are usually oriented perpendicular to the weld face and run along the plane that bisects the welded joint. Seldom are they open at the edge of the joint face, because this requires a fillet weld with an extremely convex bead.

Crater cracks (No. 1, Fig. 6) are related to centerline cracks. As the name implies, crater cracks occur in the weld crater formed at the end of a welding pass. Generally, this type of crack is caused by failure to fill the crater before breaking the arc. When this happens, the outer edges of the crater cool rapidly, producing stresses sufficient to crack the interior of the crater. This type of crack may be oriented longitudinally or transversely or may occur as a number of intersecting cracks forming the shape of a star. Longitudinal crater cracks can propagate along the axis of the weld to form a centerline crack. In addition, such cracks may propagate upward through the weld if they are not removed before subsequent passes are applied.

Hat cracks (No. 9, Fig. 6) derive their name from the shape of the weld cross section with which they are usually associated. This type of weld flares out near the weld face, resembling an inverted top hat. Hat cracks are the result of excessive voltage or welding speed. The cracks are located about halfway up through the weld and extend into the weld metal from the fusion line of the joint.

Toe and root cracks (No. 5 and 8, Fig. 6) can occur at the notches present at notch locations in the weld when high residual stresses are present. Both toe and root cracks propagate through the brittle HAZ before they are arrested in more ductile regions of the base metal. Characteristically, they are oriented almost perpendicular to the base metal surface and run parallel to the weld axis.

Lamellar tearing is the phenomenon that occurs in T-joints that are fillet welded on both sides. This condition, which occurs in the base metal or HAZ of restrained weld joints, is characterized by a steplike crack parallel to the rolling plane. The crack originates internally because of tensile strains produced by the contraction of the weld metal and the surrounding HAZ during cooling. Figure 7 shows a typical condition.

Fig. 7 Lamellar tear caused by thermal contraction strain

Fusion-line cracks (No. 7, Fig. 6) can be classified as either weld metal cracks or base metal cracks because they occur along the fusion line between the two. There are no limitations as to where along the fusion line these cracks can occur or how far around the weld they can extend.

Discontinuities Associated With Specialized Welding Processes

The preceding section has dealt mainly with the discontinuities common to conventional arc-welding processes. In addition, there are certain more specialized welding methods that may have discontinuities unique to them. These methods include electron beam, plasma arc, electroslog, friction, and resistance welding. In general, the types of discontinuities associated with these processes are the same as those associated with conventional arc welding; however, because of the nature of the processes and the joint configurations involved, such discontinuities may be oriented differently from those previously described, or they may present particular problems of location and evaluation.

Electron Beam Welding

In electron beam welding, as in all other welding processes, weld discontinuities can be divided into two major categories:

- Those that occur at, or are open to, the surface
- Those that occur below the surface

Surface flaws include undercut, mismatch, underfill, reinforcement, cracks, missed seams, and LOP. Subsurface flaws include porosity, massive voids, bursts, cracks, missed seams, and LOP. Figure 8 shows poor welds containing these flaws, and a good weld with none of them.

Fig. 8 Electron beam welds showing flaws that can occur in poor welds and the absence of flaws in a good weld with reinforcement

Surface discontinuities such as undercut, mismatch, reinforcement, and underfill are macroscopic discontinuities related to the contour of the weld bead or the joint. As such, they are readily detected visually or dimensionally. Surface discontinuities such as cracks are usually detected visually using liquid penetrant inspection or using magnetic particle inspection if the material is ferromagnetic.

When liquid penetrants are used to inspect a weld for surface discontinuities such as cracks, missed seams, and LOP, the surface to be inspected must be clean and the layers of metal smeared from machining or peened from grit- or sandblasting must be removed. Generally, some type of etching or pickling treatment works well, but the possibility of hydrogen pickup from the treatment must be considered.

Occasionally, special inspection procedures must be employed to detect some types of surface discontinuities. Missed seams and LOP are often difficult to detect because they are frequently associated with complex weld joints that prevent direct viewing of the affected surface.

Because of this difficulty, missed seams are often detected using a visual witness-line procedure, in which equally spaced parallel lines are scribed on both sides of the unwelded joint at the crown and root surfaces. Missed seams, which result from misalignment of the electron beam with the joint such that the fusion zone fails to encompass the entire joint, are detected by observing the number of witness lines remaining on either side of the weld bead. By establishing the relationship between the width of the fusion zone and the spacing of the witness lines, reasonably accurate criteria for determining whether the joint has been contained within the weld path (and therefore whether missed seams are present) can be developed.

Lack of penetration discontinuities occur when the fusion zone fails to penetrate through the entire joint thickness, resulting in an unbonded area near the root of the joint. These discontinuities are best detected by etching the root surface and observing the macroscopic shape and width of the fusion zone for full and even penetration.

An alternative method for inspecting complete weld penetration is that of immersion pulse-echo ultrasonic testing. The planet gear carrier assembly shown in Fig. 9(a) consists of three decks (plates) and eight curved spacer sections. The assembly, which is made from SAE 15B22M boron-treated structural steel, is held together by 16 welds. Weld integrity is monitored by ultrasonic methods.

Fig. 9 Planet gear carrier assembly (a) showing the four welds in one stock that connect the three decks. The top and top-center welds are tested by the top ultrasonic transducer, and the bottom and bottom-center welds are inspected by the bottom transducer. (b) Close-up of upper transducer in position to test the welds. Courtesy of John M. St. John, Caterpillar, Inc.

The parts are mounted on a turntable on a locating fixture so that the welds along the outside diameter are accessible. Two transducers, located above and below the assembly, are used. Figure 9(b) shows the upper transducer in position to test the welds. An overall view of the tank, turntable, controls, and reject/accept light panel is shown in Fig. 10. The use of such a system involves little downtime and enables a high quality level to be maintained. More information on ultrasonic test methods is presented later in this article.

Fig. 10 Overall view of the ultrasonic unit used to test the electron beam welded assembly shown in Fig. 9. Courtesy of John M. St. John, Caterpillar, Inc.

Subsurface discontinuities are generally considerably more difficult to detect than surface discontinuities because observation is indirect. The two most reliable and widely used NDI methods are radiography and ultrasonics.

Volume-type discontinuities such as porosity, voids, and bursts are detected by radiographic inspection, provided their cross sections presented to the radiating beam exceed 1 to 2% of the beam path in the metal. Discontinuities that present extremely thin cross sections to the beam path, such as cracks, missed seams, and LOP, are detectable with x-rays only if they are viewed from the end along their planar dimensions.

Ultrasonic inspection can detect most volume discontinuities as well as planar discontinuities. Planar discontinuities are best detected normal to the plane of the discontinuities, but missed seams and LOP often appear as continuous porosity when viewed looking down from the crown to the root of the weld in the plane of the discontinuity.

Because of the inherent dependence of both radiographic and ultrasonic inspection on the shape and orientation of flaws and because each of the two methods can generally detect those flaws that the other misses, it is most advisable to complement one method with the other. Furthermore, to increase the likelihood of properly viewing a flaw, one of the methods should be employed in at least two (preferably perpendicular) directions.

Plasma Arc Welding

Discontinuities that occur in plasma arc welds include both surface and subsurface types, as shown in Fig. 11.

Fig. 11 Plasma arc welds showing flaws that can occur in poor welds and the absence of flaws in good reinforced weld

Surface discontinuities such as irregular reinforcement, underfill, undercut, and mismatch that are associated with weld bead contour and joint alignment are easily detected visually or dimensionally. Lack of penetration is also detected visually through the absence of a root bead. Weld cracks that are open to the surface are detected with liquid penetrants. Surface contamination, which results from insufficient shielding-gas coverage, is detected by the severe discoloration of the weld bead or adjacent HAZ.

Subsurface discontinuities are generally more prevalent in manual than in automatic plasma arc welding and are detected primarily by radiographic or ultrasonic inspection.

Porosity is by far the most commonly encountered discontinuity. Radiographic inspection is limited to detecting pores greater than approximately 1 to 2% of the joint thickness. Visibility is greater if both the crown and root beads are machined flush. Ultrasonic inspection can detect porosity if the joint is machined flush and joint thickness exceeds approximately 1.3 mm (0.050 in.).

Tunneling, as shown in Fig. 11, is a severe void along the boundary of the fusion zone and the HAZ. This discontinuity results from a combination of torch alignment and welding conditions (particularly travel speed). Tunneling is readily detectable by radiographic inspection.

Lack of fusion discontinuities occur in either single-pass or multiple-pass repair welds (Fig. 11). These discontinuities result from insufficient heat input to permit complete fusion of a particular weld bead to the part. Incomplete fusion can be detected by radiographic or ultrasonic inspection. Depending on the orientation of the discontinuity, one method may have an advantage over the other, so both should be used for optimum inspection.

Subsurface weld cracks, regardless of their cause, are detectable by radiographic and ultrasonic inspection.

Subsurface contamination in plasma arc welding results when copper from the torch nozzle is expelled into the weld. This is caused by excessive heat, usually produced in manual repair welding when the torch nozzle is placed too close to the weld, particularly in a groove. The resulting contamination, which may be detrimental, is undetectable by conventional NDI methods. The only way of detecting copper contamination is by alerting the operator to watch for copper expulsion, which then must be machined out.

Electroslag Welding

Electroslag welding involves the use of copper dams over the open surfaces of a butt joint to hold the molten metal and the slag layer as the joint is built up vertically. Wire is fed into the slag layer continuously and is melted by the heat generated as current passes through the highly resistant slag layer.

Generally, electroslag welds are inspected with the same nondestructive examination (NDE) methods as other heavy-section welds. With the exception of procedure qualification, all testing is nondestructive because of the sizes used. Techniques such as radiography and ultrasonic inspection are most often used, while visual, magnetic particle, and liquid penetrant testing are used also. Internal defects are generally more serious. Radiography and ultrasonic tests are the best methods for locating internal discontinuities.

Because of the nature of the process, LOF is rare. If fusion is achieved on external material edges, then fusion is generally complete throughout. Cracking may occur either in the weld or the HAZ. Porosity may either take the form of a rounded or a piped shape; the latter is often called wormhole porosity. Ultrasonic inspection is probably the quickest single method for inspecting any large weldment. If defects should occur, they appear as porosity or centerline cracking. Ultrasonic inspection is effective for locating either type of defect; however, only well-qualified personnel should set up the equipment and interpret the test results.

Electroslag welding results in large dendritic grain sizes because of the slow cooling rate. Inexperienced personnel often use high sensitivity and actually pick up the large coarse grains; when such welds are sectioned, usually no defects are present. Inspectors must learn to use low sensitivity to obtain good results when inspecting electroslag welds. Magnetic particle inspection is not a particularly good inspection method, because the areas examined by this technique are primarily surface or near surface. This is only a small percentage of the total weld; the only useful information is either checking the ends for craters, cracks, or centerline cracking or possibly for lack of edge fusion on the weld faces. Usually, a visual examination gives the same result unless the defect is subsurface. Visual examinations are only effective for surface defects, which are not common in this process.

Friction Welding

If impurities are properly dispelled during upsetting, friction or inertia welds are generally free of voids and inclusions. Incomplete center fusion can occur when flywheel speed is too low, when the amount of upset is insufficient, or when mating surfaces are concave. Tearing in the HAZ can be caused by low flywheel speed or excessive flywheel size. Cracks can occur when materials that are prone to hot shortness are joined. The penetration of a split between the extruded flash into the workpiece cross section is most prevalent during the welding of thin-wall tubing using improper conditions that do not allow for sufficient material upset.

The area where LOF generally occurs is at or near the center of the weld cross section. Because this is a subsurface discontinuity, detection is limited to radiographic or ultrasonic inspection; ultrasonic inspection is more practical. The longitudinal wave test (either manual-contact or immersion method) with beam propagation perpendicular to the area of LOF gives the most reliable results. This test can be performed as long as one end of the workpiece is accessible to the transducer.

Penetration of the split between the extruded flash on the outer surface of a tube is readily detected by liquid penetrant or magnetic particle inspection after the flash has been removed by machining. A split between the weld flash on the inner surface of the tube can be detected by ultrasonic inspection using the angle-beam technique with manual contact of the transducer to the outside surface of the tube. The transducer contacts the tube so that the sound propagates along the longitudinal axis of the tube through the weldment.

Resistance Welding

Resistance welding encompasses spot, seam, and projection welding, each of which involves the joining of metals by passing current from one side of the joint to the other. The types of discontinuities found in resistance welds include porosity, LOF, and cracks. Porosity will generally be found on the centerline of the weld nugget. Lack of fusion may also be manifested as a centerline cavity. Either of these can be caused by overheating, inadequate pressure, premature release of pressure, or late application of pressure. Cracks may be induced by overheating, removal of pressure before weld quenching is completed, improper loading, poor joint fit-up, or expulsion of excess metal from the weld.

Weld Appearance. On the surface of a resistance spot welded assembly, the weld spot should be uniform in shape and relatively smooth, and it should be free of surface fusion, deep electrode indentations, electrode deposits, pits, cracks, sheet separation, abnormal discoloration around the weld, or other conditions indicating improper maintenance of electrodes or functioning of equipment. However, surface appearance is not always a good indicator of spot weld quality, because shunting and other causes of insufficient heating or incomplete penetration usually leave no visible effects on the workpiece.

The common practice for monitoring spot weld quality in manufacturing operations is the teardown method augmented with pry testing and visual inspection (Ref 1). In visual inspection, the operator uses the physical features of the weld surface, such as coloration, indentation, and smoothness, for assessing the quality of the weld. In pry testing, a wedge-shaped tool is inserted between the metal sheets next to the accessible welds, and a prying action is performed to see if the sheets will separate in the weld zone. The teardown method consists of physically tearing apart the welded members with hammers and chisels to determine the presence and size adequacy of fused metal nuggets at the spot weld site. The specifications require that the parent metal be torn and that the weld nugget remain intact. The destructiveness and/or inadequacy of these common inspection methods has long been recognized, and as a result, nondestructive methods have been extensively studied. The pulse-echo ultrasonic inspection of spot welds is now feasible and is discussed in the section "Ultrasonic Inspection" in this article. The use of acoustic emission is also discussed below.

Diffusion Bonding (Ref 2, 3, 4, 5)

Diffusion bonding is a metal joining process that requires the application of controlled pressures at elevated temperatures and usually a protective atmosphere to prevent oxidation. No melting and only limited macroscopic deformation or relative motion between the faying surfaces of the parts occur during bonding. As such, the principal mechanism for joint formation is solid-state diffusion. A diffusion aid (filler metal) may or may not be used. Terms that are also frequently used to describe the process include diffusion welding, solid-state bonding, pressure bonding, isostatic bonding, and hot press bonding. Diffusion bonding has the advantage of producing a product finished to size, with joint efficiencies approaching 100%. Details of the process are given in the article "Fundamentals of Diffusion Bonding" in *Welding, Brazing, and Soldering*, Volume 6 of the *ASM Handbook*.

Discontinuities in Diffusion Bonds. In the case of fusion welds, the detection of discontinuities less than 1 mm (0.04 in.) in size is not generally expected. In diffusion bonding, in which no major lack of bonding occurs, individual discontinuities may be only micrometers in size. To understand how discontinuities form in diffusion-bonded structures, it is first necessary to consider the principles of the process.

As illustrated in Fig. 12, metal surfaces have several general characteristics:

- Roughness
- An oxidized or otherwise chemically reacted and adherent layer
- Other randomly distributed solid or liquid products such as oil, grease, and dirt
- Adsorbed gas, moisture, or both

Because of these characteristics, two necessary conditions that must be met before a satisfactory diffusion bond can be made are:

- Mechanical intimacy of metal-to-metal contact must be achieved
- Interfering surface contaminants must be disrupted and dispersed to permit metallic bonding to occur (solvent cleaning and inert gas atmospheres can reduce or eliminate problems associated with surface contamination and oxide formation, respectively)

Fig. 12 Characteristics of a metal surface showing roughness and contaminants present. Source: Ref 5

For a given set of processing parameters, surface roughness is probably the most important variable influencing the quality of diffusion-bonded joints. The size of the discontinuities (voids) is principally determined by the scale of roughness of the surfaces being bonded. The degree of surface roughness is dependent on the material and fabrication/machining technique used. It has been shown that bonding becomes easier with finer surface roughness prior to bonding. Figure 13 compares the surface roughness values produced by a variety of fabrication methods. More detailed information on surface roughness can be found in the article "Surface Finish and Surface Integrity" in *Machining*, Volume 16 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*.

Fig. 13 Surface roughness produced by common production methods. The ranges shown are typical of the processes listed. Higher or lower values can be obtained under special conditions.

The mechanism of bond formation in diffusion bonding is believed to be the deformation of the surface roughness in order to cause metal-to-metal contact at asperities, followed by the removal of interfacial voids and cracks by diffusional and creep processes. For conventional diffusion bonding without a diffusion aid, the three-stage mechanistic model shown in Fig. 14 describes bond formation. In the first stage, deformation of the contacting asperities occurs primarily by yielding and by creep deformation mechanisms to produce intimate contact over a large fraction of the interfacial area. At the end of this stage, the joint is essentially a grain boundary at the areas of contact with voids between these areas. During the second stage, diffusion becomes more important than deformation, and many of the voids disappear as the grain-boundary diffusion of atoms continues. Simultaneously, the interfacial grain boundary migrates to an equilibrium configuration away from the original plane of the joint, leaving many of the remaining voids within the grains. In the third stage, the remaining voids are eliminated by the volume diffusion of atoms to the void surface (equivalent to diffusion of vacancies away from the void). Successful completion of stage three is dependent on proper surface processing and joint processing.

Fig. 14 Three-stage mechanistic model of diffusion welding. (a) Initial asperity contact. (b) First-stage deformation and interfacial boundary formation. (c) Second-stage grain-boundary migration and pore elimination. (d) Third-stage volume diffusion and pore elimination. Source: Ref 5

Successful nondestructive evaluation of diffusion-bonded joints requires that the maximum size and distribution of discontinuities be determined. However, many conventional NDE methods and equipment are not adequate for discontinuity determination.

Fluorescent penetrants provide excellent detection capability for lack of bonding as long as the interfacial crack breaks the surface. They are completely ineffective for defects that have no path to the surface.

Conventional film radiography is not suitable for detecting the extremely small defects involved in diffusion bonding, but the use of x-ray microfocus techniques coupled with digital image enhancement offers an improvement in resolution. Discontinuities as small as 50 μm (0.002 in.) have been detected.

Conventional ultrasonic testing has some applications, although only significant lack of bonding or clusters of smaller defects can be reliably detected. High-resolution flaw detection involving frequencies approaching 100 MHz appears to have distinct advantages over conventional testing. Scanning acoustic microscopy also appears to offer excellent possibilities in diffusion bond inspection. Eddy current and thermal methods are relatively unsatisfactory for most applications.

Methods of Nondestructive Inspection

The nondestructive inspection of weldments has two functions:

- Quality control, which is the monitoring of welder and equipment performance and of the quality of the consumables and the base materials used
- Acceptance or rejection of a weld on the basis of its fitness for purpose under the service conditions imposed on the structure

The appropriate method of inspection is different for each function. If evaluation is a viable option, discontinuities must be detected, identified, located exactly, sized, and their orientation established, which limits inspection to a volumetric technique.

Weld discontinuities constitute the center of activity with the inspection of welded constructions. The most widely used inspection techniques used in the welding industry are visual, liquid penetrant, magnetic particle, radiographic, ultrasonic, acoustic emission, eddy current, and electric current perturbation methods. Each of these techniques has specific advantages and limitations. Existing codes and standards that provide guidelines for these various techniques are based on the capabilities and/or limitations of these nondestructive methods.

Selection of Technique. A number of factors influence selection of the appropriate nondestructive test technique for inspecting a welded structure, including discontinuity characteristics, fracture mechanics requirements, part size, portability of equipment, and other application constraints. These categories, although perhaps unique to a specific inspection problem, may not clearly point the way to the most appropriate technique. It is generally necessary to exercise engineering judgment in ranking the importance of these criteria and thus determining the optimum inspection technique.

Characteristics of the Discontinuity. Because nondestructive techniques are based on physical phenomena, it is useful to describe the properties of the discontinuity of interest, such as composition and electrical, magnetic, mechanical, and thermal properties. Most significant are those properties that are most different from those of the weld or base metal. It is also necessary to identify a means of discriminating between discontinuities with similar properties.

Fracture mechanics requirements, solely from a discontinuity viewpoint, typically include detection, identification, location, sizing, and orientation. In addition, complicated configurations may necessitate a non-destructive assessment of the state of the stress of the region containing the discontinuity. In the selection process, it is important to establish these requirements correctly. This may involve consultation with stress analysts, materials engineers, and statisticians.

Often, the criteria may strongly suggest a particular technique. Under ideal conditions, such as in a laboratory, the application of such a technique might be routine. In the field, however, other factors may force a different choice of technique.

Constraints tend to be unique to a given application and may be completely different even when the welding process and metals are the same. Some of these constraints include:

- Access to the region under inspection
- Geometry of the structure (flat, curved, thick, thin)
- Condition of the surface (smooth, irregular)
- Mode of inspection (preservice, in-service, continuous, periodic, spot)
- Environment (hostile, underwater, and so on)
- Time available for inspection (high speed, time intensive)
- Reliability
- Application of multiple techniques
- Cost

Failure to consider adequately the constraints imposed by a specific application can render the most sophisticated equipment and theory useless. Moreover, for the simple or less important cases of failure, it may be unnecessary. Once criteria have been established, an optimum inspection technique can be selected, or designed and constructed.

The terms accuracy, sensitivity, and reliability are used loosely in NDE. Often, they are discussed as one term to avoid distinguishing among the specific aspects of these terminologies.

Accuracy is the attribute of an inspection method that describes the correctness of the technique within the limits of its precision. In other words, the technique is highly accurate if the indications resulting from the technique are correct. This does not mean that the technique was able to detect all discontinuities present, but rather that those indicated actually exist.

Sensitivity, on the other hand, refers to the capability of a technique to detect discontinuities that are small or that have properties only slightly different from the material in which they reside. Figure 15 schematically illustrates the concepts of accuracy and sensitivity in the context of detection probability. In general, sensitivity is gained at the expense of accuracy because high sensitivity increases the probability of false alarms.

Fig. 15 Detection probability for a true positive indication. High sensitivity increases the likelihood of false indications. The minimum NDE parameter size required to establish fitness-for-purpose must lie to the right of the transition region, or reliability threshold, to achieve satisfactory reliability.

Reliability is a combination of both accuracy and sensitivity. Three factors influence reliability: inspection procedure, including the instrumentation; human factors (inspector motivation, experience, training, education, and so on); and data analysis. Uncalibrated equipment, improper application of technique, and inconsistent quality of accessory equipment (transducers, couplant, film, chemicals, and so on) may affect accuracy and, in some cases, sensitivity. Poor inspector technique, unfamiliar response, lack of concentration, and other human factors can combine to reduce reliability. Data analysis, or the lack of it, can influence reliability as well; generally, inspection is performed under conditions in which detection probability is less than 100% and is not constant with discontinuity severity. Consequently, statistics must be employed to establish the level of confidence that may be attached to the inspection results.

High sensitivity with low accuracy may be far worse, from the viewpoint of reliability, than low sensitivity with high accuracy, especially if the sensitivity level is adequate for detecting the weld discontinuities in question. As a general rule, the transition region of the detection probability curve indicates the degree of reliability. If this region occurs within the limits encompassed by inspection capabilities, which are smaller than the values required for evaluating the fitness-for-purpose of the welds being inspected, reliability is satisfactory. If, on the other hand, the region occurs at values higher than those required, reliability is unsatisfactory. The transition region can be viewed as the reliability threshold. More detailed information on the reliability of nondestructive test data can be found in the Section "Quantitative Nondestructive Evaluation" in this Volume.

Visual Inspection

For many noncritical welds, integrity is verified principally by visual inspection. Even when other nondestructive methods are used, visual inspection still constitutes an important part of practical quality control. Widely used to detect discontinuities, visual inspection is simple, quick, and relatively inexpensive. The only aids that might be used to determine the conformity of a weld are a low-power magnifier, a borescope, a dental mirror, or a gage. Visual inspection can and should be done before, during, and after welding. Although visual inspection is the simplest inspection method to use, a definite procedure should be established to ensure that it is carried out accurately and uniformly.

Visual inspection is useful for checking the following:

- Dimensional accuracy of weldments
- Conformity of welds to size and contour requirements
- Acceptability of weld appearance with regard to surface roughness, weld spatter, and cleanliness
- Presence of surface flaws such as unfilled craters, pockmarks, undercuts, overlaps, and cracks.

Although visual inspection is an invaluable method, it is unreliable for detecting subsurface flaws. Therefore, judgment of weld quality must be based on information in addition to that afforded by surface indications.

Additional information can be gained by observations before and during welding. For example, if the plate is free of laminations and properly cleaned and if the welding procedure is followed carefully, the completed weld can be judged on the basis of visual inspection. Additional information can also be gained by using other NDI methods that detect subsurface and surface flaws.

Dimensional Accuracy and Conformity. All weldments are fabricated to meet certain specified dimensions. The fabricator must be aware of the amount of shrinkage that can be expected at each welded joint, the effect of welding sequence on warpage or distortion, and the effect of subsequent heat treatment used to provide dimensional stability of the weldment in service. Weldments that require rigid control of final dimensions usually must be machined after welding. Dimensional tolerances for as-welded components depend on the thickness of the material, the alloy being welded, the overall size of the product, and the particular welding process used.

The dimensional accuracy of weldments is determined by conventional measuring methods, such as rules, scales, calipers, micrometers, and gages. The conformity of welds with regard to size and contour can be determined by a weld gage. The weld gage shown in Fig. 16 is used when visually inspecting fillet welds at 90° intersections. The size of the fillet weld, which is defined by the length of the leg, is stamped on the gage. The weld gage determines whether or not the size of the fillet weld is within allowable limits and whether there is excessive concavity or convexity. This gage is designed for use on joints between surfaces that are perpendicular. Special weld gages are used when the surfaces are at angles other than 90°. For groove welds, the width of the finished welds must be in accordance with the required groove angle, root face, and root opening. The height of reinforcement of the face and root must be consistent with specified requirements and can be measured by a weld gage.

A	Minimum allowable length of leg
---	---------------------------------

<i>B</i>	Maximum allowable length of leg
<i>C</i>	1.414 times maximum allowable throat size (specifies maximum allowable convexity)
<i>D</i>	Maximum allowable length of leg when maximum allowable concavity is present
<i>E</i>	<i>A</i> plus <i>B</i> plus nominal weld size (or nominal length of leg)
<i>F</i>	Minimum allowable throat size (specifies maximum allowable concavity)
<i>T</i>	Additional tolerance for clearance of gage when placed in the fillet

Fig. 16 Gage for visual inspection of a fillet weld at a 90° intersection. Similar gages can be made for other angles. Dimension given in inches

Appearance Standards. The acceptance of welds with regard to appearance implies the use of a visual standard, such as a sample weldment or a workmanship standard. Requirements as to surface appearance differ widely, depending on the application. For example, when aesthetics are important, a smooth weld that is uniform in size and contour may be required.

The inspection of multiple-pass welds is often based on a workmanship standard. Figure 17 indicates how such standards are prepared for use in the visual inspection of groove and fillet welds. The workmanship standard is a section of a joint similar to the one in manufacture, except that portions of each weld pass are shown. Each pass of the production weld is compared with corresponding passes of the workmanship standard.

Fig. 17 Workmanship standard for visual comparison during inspection of single-V-groove welds and fillet welds. Dimensions given in inches

Discontinuities. Before a weld is visually inspected for discontinuities such as unfilled craters, surface holes, undercuts, overlaps, surface cracks, and incomplete joint penetration, the surface of the weld should be cleaned of oxides and slag. Cleaning must be done carefully. For example, a chipping hammer used to remove slag could leave hammer marks that can hide fine cracks. Shotblasting canpeen the surface of relatively soft metals and hide flaws. A stiff wire brush and sandblasting have been found to be satisfactory for cleaning surfaces of slag and oxides without marring.

Additional information on the uses and equipment associated with the visual examination of parts and assemblies is available in the article "Visual Inspection" in this Volume.

Magnetic Particle Inspection

Magnetic particle inspection is a nondestructive method of detecting surface and near-surface flaws in ferromagnetic materials. It consists of three basic operations:

- Establishing a suitable magnetic field in the material being inspected
- Applying magnetic particles to the surface of the material
- Examining the surface of the material for accumulations of the particles (indications) and evaluating the serviceability of the material

Capabilities and Limitations. Magnetic particle inspection is particularly suitable for the detection of surface flaws in highly ferromagnetic metals. Under favorable conditions, those discontinuities that lie immediately under the surface are also detectable. Nonferromagnetic and weakly ferromagnetic metals, which cannot be strongly magnetized, cannot be inspected by this method. With suitable ferromagnetic metals, magnetic particle inspection is highly sensitive and produces readily discernible indications at flaws in the surface of the material being inspected. Details on the application of this method are available in the article "Magnetic Particle Inspection" in this Volume.

The types of weld discontinuities normally detected by magnetic particle inspection include cracks, LOP, LOF, and porosity open to the surface. Linear porosity, slag inclusions, and gas pockets can be detected if large or extensive or if smaller and near the surface. The recognition of patterns that indicate deep-lying flaws requires more experience than that required to detect surface flaws.

Nonrelevant indications that have no bearing on the quality of the weldment may be produced. These indications are magnetic particle patterns held by conditions caused by leakage fields. Some of these conditions are:

- Particles held mechanically or by gravity in surface irregularities
- Adherent scale or slag
- Indications at a sharp change in material direction, such as sharp fillets and threads
- Grain boundaries. Large grain size in the weld metal or the base metal may produce indications
- Boundary zones in welds, such as indications produced at the junction of the weld metal and the base metal. This condition occurs in fillet welds at T-joints, or in double-V-groove joints, where 100% penetration is not required
- Flow lines in forgings and formed parts
- Brazed joints. Two parts made of a ferromagnetic material joined by a nonferromagnetic material will produce an indication
- Different degrees of hardness in a material, which will usually have different permeabilities that may create a leakage field, forming indications

Operational Requirements. The magnetic particle inspection of weldments requires that the weld bead be free of scale, slag, and moisture. For maximum sensitivity, the weld bead should be machined flush with the surface; however, wire brushing, sandblasting, or gritblasting usually produces a satisfactory bead surface. If the weld bead is rough, grinding will remove the high spots.

Weldments are often inspected using the dry particle method. A powder or paste of a color that gives the best possible contrast to the surface being inspected should be used.

The type of magnetizing current used depends on whether there are surface or subsurface discontinuities. Alternating current is satisfactory for surface cracks, but if the deepest possible penetration is essential, direct current, direct current with surge, or half-wave rectified alternating current is used.

The voltage should be as low as practical to reduce the possibility of damage to the surface of the part from overheating or arcing at contacts. Another advantage of low voltage is freedom from arc flashes if a prod slips or is withdrawn before the current is turned off.

The field strength and flux density used must be determined for each type of weldment. An overly strong field will cause the magnetic particles to adhere too tightly to the surface and hinder their mobility, preventing them from moving to the sites of the flaws. Low field strengths result in nondiscernible patterns and failure to detect indications.

Inspections can be made using the continuous-field and residual-field methods. In the continuous-field method, magnetic particles are placed on the weldment while the current is flowing. In the residual-field method, the particles are placed on the weldment after the magnetizing current is turned off. Residual magnetic fields are weaker than continuous fields. Consequently, inspections using the residual-field method are less sensitive.

The need for the demagnetization of weldments after magnetic particle inspection must be given serious consideration. Where subsequent welding or machining operations are required, it is good practice to demagnetize. Residual magnetism may also hinder cleaning operations and interfere with the performance of instruments used near the weldment.

Liquid Penetrant Inspection

Liquid penetrant inspection is capable of detecting discontinuities open to the surface in weldments made of either ferromagnetic or nonferromagnetic alloys, even when the flaws are generally not visible to the unaided eye. Liquid penetrant is applied to the surface of the part, where it remains for a period of time and penetrates into the flaws. For the correct usage of liquid penetrant inspection, it is essential that the surface of the part be thoroughly clean, leaving the openings free to receive the penetrant. Operating temperatures of 20 to 30 °C (70 to 90 °F) produce optimum results. If the part is cold, the penetrant may become chilled and thickened so that it cannot enter very fine openings. If the part or the penetrant is too hot, the volatile components of the penetrant may evaporate, reducing the sensitivity.

After the penetrating period, the excess penetrant remaining on the surface is removed. An absorbent, light-colored developer is then applied to the surface. This developer acts as the blotter, drawing out a portion of the penetrant that had previously seeped into the surface openings. As the penetrant is drawn out, it diffuses into the developer, forming indications that are wider than the surface openings. The inspector looks for these colored or fluorescent indications against the background of the developer. Details of the mechanics of this method are given in the article "Liquid Penetrant Inspection" in this Volume.

Radiographic Inspection*

Radiography is a nondestructive method that uses a beam of penetrating radiation such as x-rays and γ -rays (see the article "Radiographic Inspection" in this Volume). When the beam passes through a weldment, some of the radiation energy is absorbed, and the intensity of the beam is reduced. Variations in beam intensity are recorded on film or on a screen when a fluoroscope or an image intensifier is used. The variations are seen as differences in shading that are typical of the types and sizes of any discontinuities present. Radiography is used to detect subsurface discontinuities as well as those that are open to the surface.

Penetrameters. Most U.S. codes and specifications for radiographic inspection require that the sensitivity to a specific flaw size be indicated on each radiograph. Sensitivity is determined by placing a penetrameter (image-quality indicator) that is made of substantially the same material as the specimen directly on the specimen, or on a block of identical material of the same thickness as the specimen, prior to each exposure.

The penetrameters are usually placed on the side of the specimen nearest the source, parallel and adjacent to the weld at one end of the exposed length, with the small holes in the penetrameter toward the outer end. Penetrameter thickness is usually specified to be 2% of the specimen thickness (through the weld zone), although 1 and 4% penetrameter thicknesses are also common. American Society for Testing and Materials and American Society of Mechanical Engineers plaque-type penetrameters have three small drilled holes, whose diameters equal one, two, and four times the penetrameter thickness. Image quality is determined by the ability to distinguish both the outline of the penetrameter and one or more of the drilled holes on the processed radiograph; for example, 2-2T sensitivity is achieved when a 2% penetrameter and the hole that has a diameter of twice the penetrameter thickness are visible. Also, the image of raised numbers that identify the actual thickness (not the percentage thickness) of a penetrameter should appear clearly, superimposed on the image of the penetrameter.

Surface discontinuities that are detectable by radiography include undercuts (Fig. 18 and 19), longitudinal grooves, concavity at the weld root (Fig. 20 and 21), incomplete filling of grooves, excessive penetration (Fig. 22), offset or mismatch (Fig. 23 and 24), burn-through (Fig. 25), irregularities at electrode-change points, grinding marks, and electrode spatter. Surface irregularities may cause density variations on a radiograph. When possible, they should be removed before a weld is radiographed. When impossible to remove, they must be considered during interpretation.

Fig. 18 External undercut, which is a gouging out of the piece to be welded, alongside the edge of the top or external surface of the weld. Radiographic image: An irregular darker density along the edge of the weld image. The density will always be darker than the density of the pieces being welded. Welding process: SMAW. Source: E.I. Du Pont de Nemours & Company, Inc.

Fig. 19 Internal (root) undercut, which is a gouging out of the parent metal, alongside the edge of the bottom or internal surface of the weld. Radiographic image: An irregular darker density near the center of the width of the weld image and along the edge of the root pass image. Welding process: SMAW. Source: E.I. Du Pont de

Fig. 20 External concavity or insufficient fill, which is a depression in the top of the weld, or cover pass, indicating a thinner-than-normal section thickness. Radiographic image: A weld density darker than the density of the pieces being welded and extending across the full width of the weld image. Welding process: SMAW. Source: E.I. Du Pont de Nemours & Company, Inc.

Fig. 21 Internal concavity (suck back), which is a depression in the center of the surface of the root pass. Radiographic image: An elongated irregular darker density with fuzzy edges, in the center of the width of the weld image. Welding process: GTAW-SMAW. Source: E.I. Du Pont de Nemours & Company, Inc.

Fig. 22 Excessive penetration (icicles, drop-through), which is extra metal at the bottom (root) of the weld. Radiographic image: A lighter density in the center of the width of the weld image, either extended along the weld or in isolated circular drops. Welding process: SMAW. Source: E.I. Du Pont de Nemours & Company, Inc.

Fig. 23 Offset or mismatch with LOP, which is a misalignment of the pieces to be welded and insufficient filling of the bottom of the weld or root area. Radiographic image: An abrupt density change across the width of the weld image with a straight longitudinal darker-density line at the center of the width of the weld image along the edge of the density change. Welding process: SMAW. Source: E.I. Du Pont de Nemours & Company, Inc.

Fig. 24 Offset or mismatch (high-low), which is a misalignment of the pieces to be welded. Radiographic image: An abrupt change in film density across the width of the weld image. Welding process: SMAW. Source: E.I. Du Pont de Nemours & Company, Inc.

Fig. 25 Burn-through, which is a severe depression or a crater-type hole at the bottom of the weld but usually not elongated. Radiographic image: A localized darker density with fuzzy edges in the center of the width of the weld image. It may be wider than the width of the root pass image. Welding process: SMAW. Source: E.I. Du Pont de Nemours & Company, Inc.

Undercuts result in a radiographic image of a dark line of varying width and density. The darkness or density of the line indicates the depth of the undercut.

Longitudinal grooves in the surface of weld metal produce dark lines on a radiograph that are roughly parallel to the weld seam but are seldom straight. These dark lines have diffused edges and should not be mistaken for slag lines, which are narrow and more sharply defined.

Concavity at the weld root occurs only in joints that are welded from one side, such as pipe joints. It appears on the radiograph as a darker region than the base metal.

If weld reinforcement is too high, the radiograph shows a lighter line down the weld seam. There is a sharp change in image density where the reinforcement meets the base metal. Weld reinforcements not ground completely smooth show irregular densities, often with sharp borders. When excess metal is deposited on a final pass, it may overlap the base metal, causing LOF at the edge of the reinforcement. Although there is a sharp change in image density between reinforcement and base metal, the edge of the reinforcement image is usually irregular.

Irregularities at electrode-change points may be either darker or lighter than the adjacent areas.

Grinding marks appear as darker areas or lines in relation to the adjacent areas in the radiograph. Electrode spatter will appear as globular and lighter on the radiograph and should be removed before radiographic inspection.

As material thickness increases, radiography becomes less sensitive as an inspection method. Thus, for thick material, other NDI methods are used before, during, and after welding on both the base metal and weld metal.

Subsurface discontinuities detectable by radiography include gas porosity (Fig. 26, 27, 28), slag inclusions (Fig. 29 and 30), cracks (Fig. 31, 32, 33), LOP (Fig. 34), LOF (Fig. 35 and 36), and tungsten inclusions (Fig. 37). On a radiograph, a pore appears as a round or oval dark spot with or without a rather sharp tail. The spots caused by porosity are often of varying size and distribution. A wormhole appears as a dark rectangle if its long axis is perpendicular to the radiation beam, and it appears as two concentric circles, one darker than the other, if the long axis is parallel to the beam. Linear porosity is recorded on radiographs as a series of round dark spots along a line parallel to the direction of welding.

Fig. 26 Root pass aligned porosity, which involves rounded and elongated voids in the bottom tom of the weld aligned along the weld centerline. Radiographic image: Rounded and elongated darker-density spots, which may be connected, in a straight line in the center of the width of the weld image. Welding process: GMAW. Source: E.I. Du Pont de Nemours & Company, Inc.

Fig. 34 Lack of penetration, which occurs when the edges of the pieces have not been welded together, usually at the bottom of single-V-groove welds. Radiographic image: A darker-density band, with very straight parallel edges, in the center of the width of the weld image. Welding process: SMAW. Source: E.I. Du Pont de Nemours & Company, Inc.

Fig. 35 Lack of sidewall fusion, which involves elongated voids between the weld beads and the joint surfaces to be welded. Radiographic image: Elongated parallel, or single, darker-density lines, sometimes with darker-density spots dispersed along the LOF lines, which are very straight in the lengthwise direction and not winding like elongated slag lines. Although one edge of the LOF lines may be very straight as with LOP, lack of sidewall fusion images will not be in the center of the width of the weld image. Welding process: GMAW. Source: E.I. Du Pont de Nemours & Company, Inc.

Fig. 36 Interpass cold lap, which involves LOF areas along the top surface and edge of lower passes. Radiographic image: Small spots of darker densities, some with slightly elongated tails, aligned in the welding direction and not in the center of the width of the weld image. Welding process: GMAW. Source: E.I. Du Pont de Nemours & Company, Inc.

Fig. 37 Tungsten inclusions, which are random bits of tungsten fused into but not melted into the weld metal. Radiographic image: Irregularly shaped, lower-density spots randomly located in the weld image. Welding process: GTAW. Source: E.I. Du Pont de Nemours & Company, Inc.

Slag inclusions appear along the edge of a weld as irregular or continuous dark lines on the radiograph. Voids are sometimes present between weld beads because of irregular deposition of metal during multiple-pass welding. These voids have a radiographic appearance that resembles slag lines.

The radiographic image of a crack is a dark narrow line that is generally irregular. If the plane of the crack is in line with the radiation beam, its image is a fairly distinct line. If the plane is not exactly in line with the radiation beam, a faint dark linear shadow results. In this case, additional radiographs should be taken at other angles.

Lack of penetration shows on a radiograph as a very narrow dark line near the center of the weld. The narrowness can be caused by drawing together of the plates being welded, and the LOP may be very severe. Slag inclusions and gas holes are sometimes found in connection with LOP and cause the line to appear broad and irregular.

The radiographic image of incomplete fusion shows a very thin, straight dark line parallel to and on one side of the weld image. Where there is doubt, additional radiographs should be made with the radiation beam parallel to the bevel face. This will increase the possibility of the LOF appearing on the radiograph.

Tungsten inclusions appear either as single light spots or as clusters of small light spots. The spots are usually irregular in shape, but sometimes a rectangular light spot will appear.

Real-time radiography, which involves the display of radiographic images on television monitors through the use of an image converter and a television camera, is a rapidly developing method for weld inspection (Ref 6). One of the main advantages of real-time radiography for weld inspection is the cost savings that results from reducing the use of x-ray films. However, the possibility of expanding such an inspection system to include automatic defect evaluation by the image-processing system can yield significantly greater advantages. Automatic defect evaluation systems will result in objective and reproducible x-ray inspection, independent of human factors. Until now, the human brain has been much faster in analyzing and classifying the large range of flaw types found in welded joints. Computer programs for the efficient automated evaluation of weld radiographs are currently being developed and refined. More detailed information on the application of real-time systems for weld inspection can be found in the article "Radiographic Inspection" in this Volume.

Ultrasonic Inspection

In ultrasonic inspection, a beam of ultrasonic energy is directed into a specimen, and either the energy transmitted through the specimen is measured or the energy reflected from interfaces is indicated. Normally, only the front (entry) and back surfaces plus discontinuities within the metal produce detectable reflections, but in rare cases, the HAZs or the weld itself may act as reflecting interfaces.

Scanning Techniques. Figure 38 shows how a shear wave from an angle-beam transducer progresses through a flat testpiece--by reflecting from the surfaces at points called nodes. The linear distance between two successive nodes on the same surface is called the skip distance and is important in defining the path over which the transducer should be moved for reliable and efficient scanning of a weld. The skip distance can be easily measured by using a separate receiving transducer to detect the nodes or by using an angle-beam test block, or it can be calculated. Once the skip distance is known, the region over which the transducer should be moved to scan the weld can be determined. This region should extend the entire length of the weld at a distance from the weld line of approximately $\frac{1}{2}$ to 1 skip distance, as shown in Fig. 39. A zigzag scanning path is used, either with sharp changes in direction (Fig. 39) or with squared changes (Fig. 40).

Fig. 38 Sound beam path in a flat testpiece being ultrasonically inspected with a shear wave from an angle-beam transducer, showing the skip distance between the nodes where the beam reflects from the surfaces

Fig. 39 Three positions of the contact type of transducer along the zigzag scanning path used during ultrasonic inspection of welded joints. The movement of the sound beam path across the weld is shown on a section taken along the centerline of the transducer as it is moved from the far left position in the scanning path (a), through an intermediate position (b), to the far right position (c).

Fig. 40 Ultrasonic scanning procedures to detect longitudinal and transverse discontinuities in welds that (a) are not ground flush and (b) are ground flush

To detect longitudinal discontinuities in full-penetration butt and corner welds that are not ground flush, the transducer is oscillated to the left and right in a radial motion, with an included angle of approximately 30°, while scanning perpendicularly toward the weld, as shown in Fig. 40(a). The longitudinal movement necessary to advance the transducer parallel to the weld should not exceed 75% of the active width of the transducer per transverse scan. The weld should be scanned from both sides on one surface or from one side on both surfaces to ensure that nonvertically oriented flat discontinuities are detected. This type of discontinuity can be distinguished from vertically oriented flat discontinuities because the signal amplitudes from the two sides are different.

To detect transverse discontinuities in welds that are not ground flush, the transducer is placed on the base metal surface at the edge of the weld. The sound beam is directed by angling the transducer approximately 15° toward the weld from the longitudinal-weld axis, as shown in Fig. 40(a). Scanning is performed by moving the transducer along the edge of the weld either in one direction along both sides of the weld or in opposite directions along one side of the weld.

To detect longitudinal discontinuities in welds that are ground flush, the transducer is oscillated to the left and right in a radial motion, with an included angle of approximately 30°, while scanning across the weld as shown in Fig. 40(b). The longitudinal movement necessary to advance the transducer parallel to the weld must not exceed 75% of the active width of the transducer per transverse scan. When possible, the weld is scanned from one surface on two sides of the weld. When this is not possible, the weld can be scanned from one side on two surfaces or from one side on one surface using at least one full skip distance.

To detect transverse discontinuities in welds that are ground flush, the transducer is oscillated to the left and right in a radial motion, with an included angle of approximately 30° , as shown in Fig. 40(b), while scanning along the top of the weld from two opposing directions. If the width of the weld exceeds the width of the transducer, parallel scans should be performed, with each succeeding scan overlapping the previous one by a minimum of 25% of the active width of the transducer.

The entire volume of full-penetration welds in corner joints should be scanned with shear waves by directing the sound beam toward, or across and along, the axis of the weld, as shown in Fig. 41. If longitudinal wave testing is utilized, the weld is scanned by moving the transducer over the weld with overlapping paths. Each succeeding scan should overlap the previous scan by at least 25% of the active width of the transducer.

Fig. 41 Ultrasonic scanning procedure for full-penetration groove weld (a) and double-fillet welds (b) in corner joints

For the detection of discontinuities in the root area in T-joints (such as lack of root fusion), the width of the inspection zone should be limited to the thickness of the attachment member. The width of the inspection zone is located using ultrasonics or mechanical means and marked on the test surface. Shear-wave scanning for discontinuities in the base metal of any T-joint configuration should be performed whenever the surface opposite the attachment member is accessible. This scanning procedure can also be applied to partial-penetration welds in T-joints.

Coverage in each direction begins from the nearest section of the joint to beyond the centerline of the weld. The angle-beam transducer is directed at the particular area of interest and oscillated to the left and right in a radial motion, with an included angle of approximately 30°, while scanning perpendicularly toward the inspection zone. The inspection zone depth should be limited to the through-member-plate thickness minus 6 mm ($\frac{1}{4}$ in.). The movement necessary to advance the transducer parallel to the inspection zone should not exceed 75% of the active width of the transducer per perpendicular scan.

Discontinuity Signals. Cracks and LOF discontinuities present essentially flat reflectors to the ultrasonic beam. If the beam is perpendicular to the place of the discontinuity, the amplitude of the signal is high; but if the beam strikes the discontinuity at an angle, most of the ultrasonic energy is reflected away from the transducer, and the reflected signal has a small amplitude that will vary with the angle. Because both cracks and sidewall LOF discontinuities produce similar reflected signals, they cannot be distinguished from one another by the signal amplitude or signal shape on the viewing screen when scanning is done from only one side. Therefore, the weld should be inspected from two sides, as shown in Fig. 42. If the discontinuity is vertically oriented, such as a centerline crack would be, the reflected signals received during a scan of each side should have approximately the same amplitude. If the discontinuity is in an inclined position, such as a sidewall LOF discontinuity would be in many joint designs, there will be an appreciable difference between the signal amplitudes.

Fig. 42 Transducer scanning positions for distinguishing between weld metal flaws that are (a) vertically oriented and (b) in an inclined position

A slag inclusion in a butt weld may produce a reflected signal with the same amplitude as that received from a crack or LOF discontinuity. However, scattered ultrasonic energy produces a relatively wide and high signal; as the transducer is manipulated around the slag inclusion, the signal height does not decrease significantly, but the edges of the signal vary. The same shape of reflected signal should be displayed when the weld is scanned from the opposite side of the weldment.

The signals that are reflected from porosity (gas pockets) are usually small and narrow. The signal amplitude will vary if the transducer is manipulated around the gas pocket or if the gas pocket is scanned from the opposite side of the weld. Cluster porosity (groups of gas pockets, as shown in Fig. 27) usually produces displays with a number of small signals. Depending on the number of gas pockets and their orientation to the ultrasonic beam, the displayed signals will be stationary or will be connected with one another.

Lack of fusion, weld root cracks, and LOP give essentially the same type of signal on an oscilloscope screen; the reflected signals are narrow and appear at the same location. The best way to differentiate among these flaws is to determine the extent of the flaw in the transverse direction.

Weld undercutting is distinguishable from sidewall LOF. The signals reflected from undercutting are approximately equal in amplitude when scanned from both sides. The signals produced by a sidewall LOF discontinuity vary considerably in amplitude when scanned from both sides.

In many cases, a weld is made when two misaligned parts must be joined; this condition is termed weld mismatch (Fig. 23 and 24). The inspector must not confuse a signal reflected from a root crack with one reflected from the misaligned edge. A narrow signal is usually produced when the ultrasonic beam strikes the misaligned edge. In most cases, no reflected signal will be received if the misaligned edge is scanned from the opposite side.

Ultrasonic Inspection of Spot Welds in Thin-Gage Steel. With the development of high-frequency transducers (12 to 20 MHz), pulse-echo ultrasonic inspection of spot welds in very thin gage sheet metal (0.58 mm, or 0.023 in.) is now possible (Ref 1). The ultrasonic test for spot weld nugget integrity relies on an ultrasonic wave to measure the size of the nugget. The size is in three dimensions, including thickness as well as length and breadth (or diameter for a circular spot). The successful measurement of nugget size places several requirements on the ultrasonic wave path, wave velocity, and wave attenuation.

Wave Path. The first requirement is that the ultrasonic wave be in the form of a beam directed perpendicular to the faces of the metal sheets and through the center of the nugget (Fig. 43). Two diameters of nuggets are shown: larger than the beam and smaller than the beam.

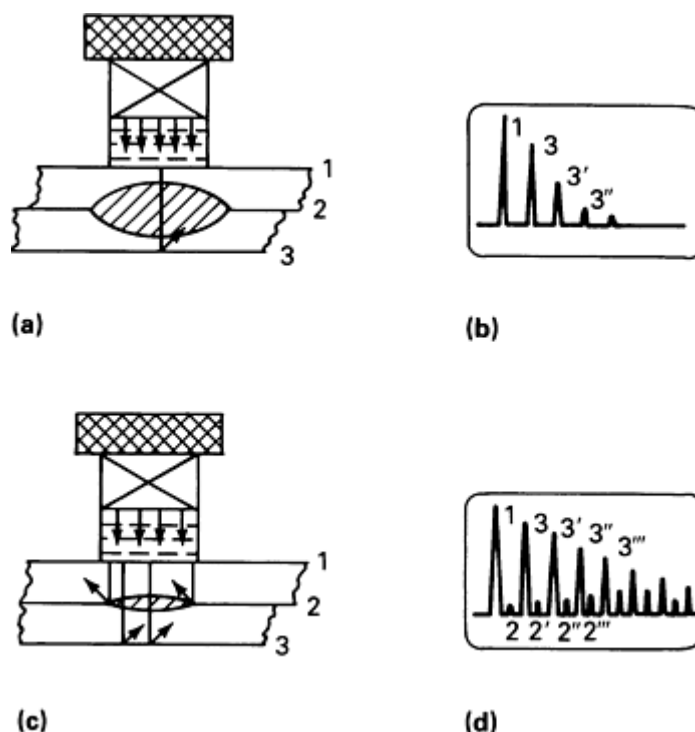

Fig. 43 Schematic illustrating setup for the pulse-echo ultrasonic inspection of resistance-welded spot welds. (a) Wave paths in satisfactory weld. (b) Resulting echoes. (c) Wave paths in an unsatisfactory weld. (d) Resulting echoes. Source: Ref 1

In general, an ultrasonic wave will be reflected when it impinges on an interface where the density and/or the ultrasonic velocity change. Examples are water-to-metal and metal-to-air. In Fig. 43, reflections will occur at the outer surfaces of the two sheets and at the interface (air) between the two sheets if the nugget is small, as in Fig. 43(c). The nugget-to-parent-metal boundary will not produce perceptible reflections, refraction, or scattering, because the changes in density and velocity are a tenth of a percent or less, while the air-to-steel difference is more than 99.9%.

Typical oscilloscope displays showing the pulse-echo patterns for these two nugget-to-beam-diameter ratios are shown in Fig. 43(b) and 43(d). The difference in the echo patterns permits the distinction to be made between adequate and undersize welds.

Velocity/Thickness Gaging. The beam path shown in Fig. 43(a) illustrates the situation in which the ultrasonic beam should indicate an acceptable nugget. The beam will be reflected only at the outer surfaces (1 and 3) of the pair of sheets as joined. To make this reflection sequence visible, the ultrasonic beam must consist of a short pulse that can reverberate back and forth between the outer faces and produce separate echoes when viewed on an oscilloscope. The picture observed is shown in Fig. 43(b). The pulse must be short enough to resolve the double thickness of the two joined sheets.

Similarly, the beam path shown in Fig. 43(c) illustrates the situation in which the ultrasonic beam should indicate an undersize nugget. The beam will be reflected in the single thickness of the upper sheet around the perimeter of the nugget. Therefore, on the oscilloscope, echoes will appear between the principal echoes arising from the portion of the beam traversing the nugget (Fig. 43d). In terms of thickness gaging, the ultrasonic pulse in the beam must be short enough to resolve the thickness of one layer of sheet metal.

Attenuation. The thickness of the nugget can be measured only indirectly because the thickness gaging function (described above) can measure only the thickness between outer faces in the nugget area. The nugget itself is measured by the effect of its grain structure on the attenuation of the ultrasonic wave in the beam. As the wave reflects back and forth between the outer faces of the welded sheets, its amplitude is attenuated (dies out). The attenuation (rate of decay) of the ultrasonic wave depends on the microstructure of the metal in the beam. In the spot welds under consideration, the attenuation is caused principally by grain scattering. The grains scatter the ultrasonic energy out of the coherent beam, causing the echoes to die away. In most metals, coarse grains scatter more strongly than fine grains.

Because a nugget is a melted and subsequently refrozen cast microstructure with coarser grains than the adjacent cold-rolled parent metal, the nugget will scatter more strongly than the remaining parent metal. It follows that a nugget will produce higher attenuation than the parent metal and that a thick nugget will result in higher attenuation than will a thin nugget. Therefore, a thin nugget can be distinguished from a thick nugget by the rate of decay of the echoes in the case in which the diameters of both nuggets are equal. Typical echoes from a thick nugget area and from a thin nugget are shown in Fig. 44. It is clear that a trained observer could differentiate between the two welds on the basis of the decay patterns. Given this observation, it is obvious that the pulse-echo ultrasonic method at normal incidence could perform the required measurements on spot welds in metals with coarse-grain nuggets and fine-grain parent sheet metal.

Acoustic Emission Monitoring

Acoustic emissions are impulsively generated small-amplitude elastic stress waves created by deformations in a material. The rapid release of kinetic energy from the deformation mechanism propagates elastic waves from the source, and these are detected as small displacements on the surface of the specimen. The emissions indicate the onset and continuation of deformation and can be used to locate the source of deformation through triangulation techniques. Details of the process are available in the article "Acoustic Emission Inspection" in this Volume.

Acoustic emissions can be used to assess weld quality by monitoring during or after welding. In weldments, regions having LOP, cracking, porosity, inclusions, or other discontinuities can be identified by detecting the acoustic emissions originating at these regions. During welding processes, acoustic emissions are caused by many factors, including plastic deformation, melting, friction, solidification, solid-solid phase transformations, and cracking. In some cases, the monitoring of acoustic emissions during welding can include automatic feedback control of the welding process. In large-scale automatic welding, the readout equipment can be conveniently located near the welder controls or in a quality-monitoring area.

The locations of acoustic sources on a weld line can be presented in a variety of ways. One technique displays the number of events versus distance along the weld on an oscilloscope screen or an x - y plotter. Another technique uses a digital-line printer that gives the time of the event, its location, and its intensity. This information facilitates appraisal of the severity of each source. Once the acoustic emission sources are graded, other NDI methods can be used to study the discontinuity in detail.

It is sometimes difficult to achieve a good acoustic coupling between the sensor (or sensors) and the part. This is especially true for welding processes that have a fixed arc and a moving part. For postweld acoustic emission monitoring, a stimulus must be applied after complete cooling of the weld. This involves the application of a mechanical load or sometimes a thermal stress to the part or structure. For the field inspection of in-service welds for cracks or other flaws, welds are commonly subjected to stresses that just exceed the maximum stress previously experienced by the weld. The excess stress is necessary to produce acoustic emissions due to plastic deformation at the crack tip. The application of this stress, however, is often difficult to do and in some cases is undesirable. An alternative method that can often clearly detect existing cracks in a weld is to cyclically load the weld at low-stress levels. The relative motions of the crack surfaces produce frictional excitation of stress waves.

Acoustic emission monitoring for evaluation of quality and control of welding processes requires preliminary studies for each application to establish such operating conditions as the number, location, and mounting of sensors; gain settings; filtering; data presentation; and data interpretation. These studies normally include correlation with other nondestructive and destructive methods of inspection. For example, the detection of tungsten inclusions from GTAW joints by acoustic emission can also involve inclusion classification by radiography.

The postweld monitoring of weldments includes both quality control inspection during the period between the completion of the weld and additional fabrication of the part and nondestructive inspection of in-service weldments. An example of the former is the inspection of butt-welded plates, such as those fabricated in the building of a ship. The following example demonstrates the feasibility of immediate postweld acoustic emission monitoring of butt-welded plates.

Example 1: Acoustic Emission Monitoring of Butt Welds in Low-Carbon Steel Plates.

Using a dc arc welder, two low-carbon steel plates 460 mm (18 in.) wide by 610 mm (24 in.) long and 3.2 mm (0.125 in.) thick were butt welded to form a test plate approximately 1.2 m (48 in.) long, as shown in Fig. 45. Extra precautions were taken to produce a sound weld. After the weld metal was cool, the plate was placed in a fixture so that acoustic emission from the weld metal could be monitored.

Fig. 45 Acoustic emission monitoring of butt welds in low-carbon steel test plates. (a) Test plate. Three were prepared; the first, with a sound weld, was used to establish conditions for acoustic emission monitoring of the others. (b) Location and number of acoustic emissions in the second test plate, which had a region of intentional poor penetration and slag inclusions (shaded area). (c) Location and number of acoustic emissions in the third test plate, in which flaw indications were revealed by radiographic inspection (shaded areas).

The plate was supported horizontally by a system of rubber rollers. Weights were placed on each end of the plate to hold it firmly on the rollers. Mild bending was induced in the butt joint by raising and lowering the middle of the plate with a hydraulic jack. Acoustic emissions were monitored during loading and unloading oscillation and while the plate was held in a stress state, using sensors attached to the top side of the plate at each end of the weld. These emissions were used to calibrate the oscilloscope screen and were the basis for subsequent inspections of plates having known or suspected discontinuities in the weld metal.

The output signal of each sensor was amplified (75-dB gain), filtered (50 kHz to 1 MHz), and displayed on a dual-beam oscilloscope. Single-sweep traces of both signals were triggered at the arrival of the first signal. These were photographed from the dual-beam display, and successive photographs permitted documentation of the difference between the arrival times at the two sensors for several sources. The locations of the predominant sources were then inferred.

After the preliminary experiments, a second test plate was prepared and butt welded across its entire width. The weld was made with intentional poor penetration and slag inclusions in a region centered about 100 mm (4 in.) on one side of the centerline of the plate, as indicated by the shaded area in Fig. 45(b). Acoustic emissions were recorded during bending and oscillation. The location and number of acoustic emissions are given graphically in Fig. 45(b). A good correlation existed between the tabulated source locations and the locations of known flaws.

A third test plate was prepared by making a saw cut 180 mm (7 in.) long, from one edge toward the center, along the transverse centerline. This saw cut was repaired by welding, then monitored for acoustic emissions in the same manner as the second test plate. Radiographic inspection of the plate revealed two regions of discontinuities in the weld, as indicated by the shaded areas in Fig. 45(c). A region of very poor penetration between 130 and 150 mm (5 and 6 in.) from the longitudinal centerline of the plate is shown by the darker shaded area in Fig. 45(c). This corresponds to the large number of acoustic emissions occurring in the region. Also shown in Fig. 45(c) are other regions from which acoustic emissions originated, indicating discontinuities in the weld metal. From the results obtained on these test plates, it was concluded that it is feasible to use acoustic emission monitoring as a method of assessing the structural integrity of butt-welded joints.

In-Service Monitoring. One application of in-service acoustic emission monitoring of welds involved the locating of defective or deteriorated welds in buried pipelines. Gas distribution pipelines that had been in service for many years needed inspections for structural integrity, especially on oxyacetylene welds. Although the location of the buried pipe was known, the locations of the welds were not. In preliminary studies, it was found that acoustic emission signals from weld discontinuities would propagate several hundred feet down the pipe. Therefore, a very efficient method of locating the defective welds was devised. The loading stimulus, an extra heavy vehicle moving slowly along the surface above the pipe, induced bending stresses that were sufficient to cause weld discontinuities to emit. Sensors were placed on either side of the suspect weld, and the signals reaching the sensors were monitored with portable equipment. By comparing the time required for the emissions to reach each pair of sensors and by comparing the intensities of the signals, the locations of the defective weld were determined. The welded joints were then excavated, and the welds were further inspected or repaired.

Monitoring During Welding. Arc-welding processes are inherently ultrasonically noisy--particularly so in continuous high-frequency welding. However, the acoustic emissions detected during proper welding without discontinuity creation have steady characteristics. When cracking, excessive slag inclusion, or a significant change in the weld conditions occurs, the acoustic emission levels change correspondingly. Therefore, online monitoring during welding gives immediate indication of variations in the quality of the weld. Cold cracking can be detected by monitoring the welded structure for minutes, or even hours, after welding.

Acoustic emissions result from multiple causes during resistance spot welding. The making of a resistance spot weld consists of setdown of the electrodes, squeeze, current flow, hold time, and lift off. Many acoustic emissions are produced during these various steps. The most commonly observed signals are shown schematically in Fig. 46. The ultrasonic noise during setdown and squeeze can be related to the conditions of the electrodes and the surface of the parts. The large, but brief, signal at current initiation can be related to the initial resistance and the cleanliness of the parts. During current flow, acoustic emission results from plastic deformation, friction, melting, and expulsions. The signals associated with expulsion (spitting and flashing) are generally large in amplitude and can be easily distinguished from the rest of the emissions associated with nugget formation. When current flow ceases, some materials exhibit appreciable solidification noise that can be related to nugget size and inclusions. As the nugget cools in the hold period, acoustic emissions can result from solid-solid phase transformations and cracking. Finally, as the electrode is lifted, noise is produced by the separation of the electrode from the part. This noise, or signal, can be related to the size of the nugget as well as to the visual appearance of the weld.

Fig. 46 Schematic showing typical acoustic emission signals obtained during various stages of resistance spot welding

Any measure of the cumulative acoustic emissions during resistance spot welding cannot be expected to relate clearly to weld quality. On the other hand, by using both time discrimination and multiple detection levels, the various segments of acoustic emissions can be separately measured and related to various indicators of quality. Commercial instrumentation is available that is capable of separately monitoring several of the acoustic emission segments. For example, the expulsion count, phase-transformation count, and cracking count can be monitored and recorded for each resistance spot weld, giving a permanent record of quality. In the following example, a number of acoustic emissions during martensitic phase transformation were found to relate to the strength of the resistance spot weld.

Example 2: Determination of Strength of Resistance Spot Welds by Acoustic Emission Monitoring.

Twenty carbon steel coupons were spot welded at identical settings of heat and weld cycles in a 75-kVA ac spot welder. An acoustic emission sensor was attached to the lower electrode. The acoustic emission monitor was gated to begin 120 ms after the current ceased and to stop 240 ms later. Within that time interval, martensitic phase transformation occurred as the nugget cooled. Because the total volume of material experiencing the transformation is related to both the nugget size and the area of diffusion bonding, the acoustic emissions during the phase transformation are related to the strength of the weld. The specimens were pulled to failure in tension shear, and the ultimate strength was recorded. The results are shown in Fig. 47. The tests indicated that a 10% variation in weld strength corresponded to about a 30% change in acoustic emissions.

Fig. 47 Relation of strength of resistance spot welds in carbon steel coupons to number of acoustic emissions

during the martensitic phase transformation

Leak Testing

Welded structures are leak tested to measure the integrity of the structure for containing gases, fluids, semisolids, and solids and for maintaining pressures and vacuums. The more common leak-testing methods used are (in order of increasing sensitivity):

- Odor from tracer gas
- Pressure change
- Pressurized liquid (generally water) and visual observation
- Pressurized gas using a leak detection solution
- Tracer gas using thermal leak detectors
- Helium using a mass spectrometer during pressure and vacuum tests

Other methods less frequently used are acoustical detection of gas flow through a leak and use of radioactive tracer gas. Detailed descriptions of the various methods used are presented in the article "Leak Testing" in this Volume.

Weld flaws that contribute to leakage of a structure are porosity, LOF or LOP, and cracks. Cracks are of particular concern because they may propagate when the structure is proof tested or otherwise tested for structural integrity. Therefore, it is preferred that leak testing be done after completion of the structural tests.

Selection of a leak testing method depends on the environment in which the structure is used and the potential danger and economic impact involved in the event of a service failure. The acceptance criteria should include a numerical expression of the allowable leak rate; the frequently used expression "shall be free from leaks" is meaningless.

Eddy Current and Electric Current Perturbation Inspection

Eddy current inspection is based on the principles of electromagnetic induction and is used to identify or to differentiate between a wide variety of physical, structural, and metallurgical conditions in electrically conductive ferromagnetic and nonferromagnetic metals. Normally, eddy current inspection is used only on thin-wall welded pipe and tubing for the detection of longitudinal-weld discontinuities, such as open welds, weld cracks, and porosity. The application of this method to tubular goods is discussed in the articles "Eddy Current Inspection," "Tubular Products," and "Boilers and Pressure Vessels" in this Volume.

The electric current perturbation method consists of establishing an electric current flow in the part to be inspected (usually by means of an induction coil) and detecting the magnetic field associated with perturbations in the current flow around defects by using a separate magnetic field sensor (Ref 7). This technique is applicable to the detection of both very small surface cracks as well as subsurface cracks in both high- and low-conductivity, nonferromagnetic materials, such as titanium and aluminum alloys. The principles, equipment, and applications associated with this method are outlined in the article "Electric Current Perturbation NDE" in this Volume.

Nondestructive Inspection of Weldments, Brazed Assemblies, and Soldered Joints

Brazed Assemblies

Brazing is defined by the American Welding Society as a group of welding processes that produce coalescence of materials by heating them to a suitable temperature and by using a filler metal having a liquidus above 450 °C (840 °F) and below the solidus of the base metal. The filler metal is distributed between the closely fitted faying surfaces of the joint by capillary action.

The temperature limitation of 450 °C (840 °F) differentiates brazing from soft soldering, which involves the use of filler metals having a liquidus below 450 °C (840 °F). To clarify the difference between brazing and conventional welding, it should be pointed out that in brazing the base materials being joined are never melted, while in most welding processes the base metals are melted (exceptions are those welding processes that utilize pressure in conjunction with heat).

There are six brazing processes included under the group heading of brazing. These processes are torch brazing, furnace brazing, induction brazing, dip brazing, resistance brazing, and infrared brazing.

Brazing can also be classified according to the major constituents of the more common types of filler metals used:

- Aluminum brazing
- Silver brazing
- Copper brazing
- Nickel brazing
- Precious metal brazing

There are five essential properties for brazing filler metal:

- Ability to wet and make a strong, sound bond on the base metal
- Suitable melting temperature and flow properties to permit distribution by capillary attraction in properly prepared joints
- A composition of sufficient homogeneity and stability to minimize separation by liquation under the brazing conditions to be encountered. Excessively volatile constituents in filler metals may be objectionable
- Capability of producing a brazed joint that will meet service requirements, such as required strength and corrosion resistance
- Depending on the requirements, ability to produce or avoid interactions between base metal and filler metal

Flaws Commonly Found in Brazed Joints

Flaws exhibited by brazed joints are usually of the following types:

- Lack of fill
- Flux entrapment
- Noncontinuous fillet
- Base metal erosion

Lack of Fill. Voids resulting from lack of fill can be the result of improper cleaning of the faying surfaces, improper clearances, insufficient brazing temperatures, or insufficient brazing filler metal (Fig. 48).

Fig. 48 Voids resulting from lack of fill between the faying surfaces of a lap joint between two sheets of Hastelloy X brazed with BNi-1 filler metal. Unetched. $16\frac{1}{2}\times$.

Flux entrapment normally occurs during torch brazing, induction brazing, or furnace brazing, when reducing atmospheres are not employed. As the term implies, flux becomes trapped within the joint by the braze metal and prevents coverage. Figure 49 is a radiograph of a torch-brazed joint in which flux entrapment was a serious problem.

Fig. 49 Radiograph showing entrapped flux (dark areas) in a low-carbon steel joint torch brazed with BAg-1 filler metal (light areas). $1\times$

Noncontinuous Fillet. A brazed joint in which a large void in the fillet is evident is shown in Fig. 50. Such a void is discernible by visual examination and may or may not be acceptable, depending on requirements. For example, if the void in the fillet did not extend through the entire braze width, the joint would still be leaktight, which was the major requirement of the brazement. On the other hand, if 100% braze fillet was needed because of stress requirements, the assembly would be unacceptable.

Fig. 50 Incomplete penetration of filler metal (BAg-1) in a brazed joint between copper components. 20×

Base Metal Erosion. Certain brazing filler metals will readily alloy with the base metals being brazed, causing the constituents of the base metal to melt and, in some cases, creating an undercut condition or the actual disappearance of the faying surfaces. This is called base metal erosion. Extreme erosion in type 304 stainless steel brazed with a nickel-chromium-boron filler metal is shown in Fig. 51; a similar joint without erosion is shown in Fig. 52. Erosion may not be serious where thick sections are to be joined, but it cannot be permitted where relatively thin sections are used.

Fig. 51 Excessive erosion of type 304 stainless steel base metal by BNi-1 filler metal. Compare with the noneroded joint shown in Fig. 52. 20×

Fig. 52 Joint between type 304 stainless steel components brazed with BNi-1 filler metal, in which no base metal erosion occurred. Note characteristic sheared edge on one component and small voids in the filler metal.

Three factors influencing base metal erosion are brazing temperature, time at temperature, and the amount of brazing filler metal available or used in making the joint. As the brazing temperature exceeds the melting point of the filler metal, interaction between the molten filler metal and the base metal accelerates. The brazing temperature should therefore be kept low, provided, of course, that it is sufficient for proper flow of the filler metal to fill the joint. Similarly, time at temperature should be kept to a minimum to prevent excessive interaction between the molten filler metal and the base metal. Finally, the amount of filler metal required to fill the joint and provide the necessary fillet size should be closely controlled. Filler metal present in excess of the amount required is likely to react with the base metal, creating severe or excessive erosion in proportion to the amount of excess filler metal.

Joint Integrity

Some form of discontinuity usually occurs in all types of brazed joints. The degree and severity vary from a minor pinhole in the filler metal to gross discontinuities. Lack of fill or flux entrapment can vary from slight to nearly 100%. Erosion of the base metal can be nonexistent or can cause complete destruction of the joint.

Requirements for brazed joints are many and varied. As with other accepted joining processes, it is important that brazed joints be properly designed and engineered for the use intended. Significant factors involved are selection of proper base metals and brazing filler metal for compatibility and strength, proper fits and clearances, proper brazing process, and cleanliness of the surface to be brazed. Furthermore, it must be determined what requirements are necessary for withstanding the service conditions to which the finished brazement will be exposed.

Primarily, brazed joints are designed for mechanical performance, electrical conductivity, or pressure-tightness. The braze quality requirements, therefore, should reflect the end use for which the joint was designed.

Methods of Inspection

Inspection of the completed assembly or subassembly is the last step in the brazing operation and is essential for ensuring satisfactory and uniform quality of the brazed unit. This inspection also provides a means for evaluating the adequacy of the design and the brazing operation with regard to ultimate integrity of the brazed unit.

Destructive methods such as peel tests, impact tests, torsion tests, and metallographic examination are initially used to determine whether the braze design meets the specified requirements. In production, these methods are employed only with random selection or lot testing of brazed joints. In lot testing, samples representing a small specified percentage of all production are tested to destruction. The results of these tests are assumed to apply to the entire production, and the joints in the various lots or batches are accepted or rejected accordingly. When used as a check on an NDI method, such as visual examination, a production part can be selected at regular intervals and the joint tested to destruction so that rigid control of brazing procedures is maintained.

The inspection method chosen to evaluate the final brazed component should depend on service and reliability requirements. In many cases, the inspection methods are specified by the ultimate user or by regulatory codes. In establishing codes or specifications for brazed joints, the same approach should be used as in the setting up of standards for any other phase of manufacturing. The standards should be based, if possible, on requirements that have been established by prior service or history.

Visual Inspection

Visual inspection is the most widely used of the nondestructive methods for evaluating brazed joints. However, as with all other methods of inspection, visual inspection will not be effective if the joint cannot be readily examined. Visual inspection is also a convenient preliminary test where other inspection methods are used.

When brazing filler metal is fed from one side of the joint or replaced within the joint at or near one side so that visual examination of the opposite side of the joint after brazing shows a continuous fillet of filler metal, it can usually be assumed that the filler metal has flowed through the joint by capillary attraction and that a sound joint has been obtained. On the other hand, if the joint can be inspected only on the side where the filler metal is applied, it is quite possible that an unsatisfactory joint has been produced, even though a satisfactory fillet is in evidence to the inspector.

Visual inspection cannot reveal internal discontinuities in a brazed joint that result from flux entrapment or lack of fill. Occasionally, gross erosion can be detected.

Proof Testing

Proof testing is a method of inspection that subjects the completed joints to loads slightly in excess of the loads to be applied during their subsequent service life. These loads can be applied by hydrostatic methods, tensile loading, spin testing, or numerous other methods. Occasionally, it is not possible to ensure a serviceable part by any of the other nondestructive methods of inspection, and proof testing then becomes the most satisfactory method.

Pressure Testing

Pressure testing of brazed assemblies is a method of leak testing and is usually confined to vessels and heat exchangers where liquid, gas, or air tightness is required. Several methods of pressure testing can be employed. Most use either air or gas, depending on the application of the vessel or heat exchanger. In most cases, the test pressures are greater than those to which the assembly will be subjected in service and are specified by the user.

One or more of the following three procedures are generally employed for pressure testing:

- All openings are closed. Air or gas is injected into the assembly until the specified pressure is reached. The inlet sources are closed off, the assembly is allowed to sit for a period of time, and pressure decreases are then measured on a gage
- All openings in the assembly are closed except one, which is fitted with an inlet-pressure line. With the assembly submerged in a tank of water, air or gas is admitted through the inlet line until a specified pressure is reached. The inspector then looks for bubbles rising through the water
- All openings are closed, and the assembly is pressurized to the specified pressure. Then a leak-detecting solution, of which there are several commercially available, is brushed on the joints to be inspected. If any of the joints leak, bubbling will occur

Vacuum-and-helium testing is generally used in inspecting assemblies where it is imperative that the most minute leak be detected. This method of inspection is often employed on nuclear reactor hardware. It is also extensively used in the inspection of refrigeration equipment.

The assembly to be inspected is connected to a vacuum system, and the vacuum is monitored by a mass spectrometer. Helium gas is flushed around the brazed joint; if any minute leak is present, the helium, because of its small molecule, will be pulled in by vacuum and register on the mass spectrometer, thus indicating the leak.

A more sensitive technique is pressurizing the assembly with helium while the assembly is contained in a sealed plastic bag. After pressurizing for a period of time (for example, 24 h), the atmosphere in the bag is analyzed for the presence of helium. Additional information on pressure testing techniques can be found in the article "Leak Testing" in this Volume.

Ultrasonic Inspection

Ultrasonic inspection, although not extensively used in the evaluation of brazed joints, can be the only method applicable in certain cases. The use of ultrasonic inspection depends largely on the design of the joint and the configuration of the adjacent areas of the brazed assembly. Advancements in ultrasonic inspection may increase the utility of this process so that brazed joints can be evaluated with reliability.

Radiographic Inspection

Radiographic inspection is commonly used for the nondestructive evaluation of brazed joints following visual examination. In almost all cases, the radiation beam is directed at about 90° to the plane of the joint, and the radiograph is taken through the thickness of the braze metal.

X-rays readily discern the differences in density between the brazing filler metal and the base metal. Care must be exercised, however, because joints between sections of varying thicknesses can produce radiographs that are misleading and difficult to interpret. Also, it is often difficult to determine whether a joint has been penetrated fully or not at all; both situations yield radiographs in which there is a full fillet visible around the joint, and the gap in the joint itself has uniform radiographic density. By contrast, partly filled joints, voids in the braze metal, and inclusions are relatively easy to find with radiography.

The filler metal in brazed joints is very thin--from 0.013 to 0.25 mm (0.0005 to 0.010 in.) in thickness. When radiographs are made of brazed joints between thick components, the process may be unable to record the braze metal as a difference in density; at least 2% difference is usually needed for good sensitivity.

Liquid Penetrant Inspection

Liquid penetrant inspection is another nondestructive method for determining the reliability of brazed joints and assemblies. This inspection method produces a visual image of a discontinuity in the surface of the braze and reveals the nature of a discontinuity without impairing the parent metal. Acceptable and unacceptable components or assemblies can be separated in accordance with predetermined standards.

There are certain advantages obtained from the liquid penetrant inspection of brazed assemblies. However, a brazed joint or component should be visually inspected first, then inspected by a liquid penetrant method to resolve any doubt concerning joint integrity.

Visual examination is restricted to those discontinuities that can be detected by the unaided eye. Liquid penetrant carries visual inspection a step further by increasing the detectability of fine cracks or openings. Discontinuities such as LOF, cracks that x-rays cannot show because of orientation, and porosity and laps become visible with this technique. Liquid penetrants do not disclose subsurface discontinuities such as voids, cracks, or flux entrapment; radiography is best used to discover such discontinuities.

Selection of the specific liquid penetrant system for the inspection of brazed assemblies depends on the same factors as those that affect system selection for other workpieces. The water-washable, postemulsifiable, and solvent-removable systems have been successfully used for inspecting brazed assemblies.

Inspection using liquid penetrants should not be performed prior to brazing unless adequate cleaning steps, such as vapor degreasing, are taken to remove entrapped penetrant fluid. If permitted to remain during the brazing cycle, this fluid can contaminate the furnace atmosphere and braze metal, producing flaws.

Inspection With Thermally Quenched Phosphors

Inspection with thermally quenched phosphors is a means of nondestructively detecting flaws such as voids and unbonded areas of laminated honeycomb brazed structures where thin (<1.6 mm, or $\frac{1}{16}$ in., thick) sheets are used. Thermally quenched phosphor powder mixed with a carrier of polyvinyl alcohol binder is sprayed onto the surface of the part to be inspected. After the surface has dried at room temperature, the part is placed in a darkened booth under a filtered ultraviolet light source. Heat is applied uniformly over the surface of the part, using a heat gun having a blower. Generally, the heat should be applied quickly. The surface of the part that was heated will initially appear uniformly dark; almost immediately, any unbonded areas of the underlying bonded structure will show up very dark on the surface. Voids or unbonded areas that appear much darker than the rest of the area should be promptly marked for later reference because as the heated surface cools, the color of the surface will become uniform.

The part can be reinspected after the surface has cooled to room temperature by reheating the surface. Phosphor coating can be removed quickly by washing in warm water, and no residue or contaminants will remain. Additional information on infrared-sensitive imaging is available in the article "Thermal Inspection" in this Volume.

Nondestructive Inspection of Weldments, Brazed Assemblies, and Soldered Joints

Soldered Joints

Soldering is a process of ensuring a permanent joint or of building up a surface on metallic parts by means of a metallic filler (solder), which is either introduced in a liquid state between the surfaces to be joined or becomes liquefied by heating below 450 °C (840 °F) and below the melting point of the base metal. The action of capillary forces causes the liquid solder to fill the gap between the faces of the parts being joined. A temperature of about 450 °C (840 °F) is usually accepted as the upper limit of the melting temperature of solder. Detailed information on soldering alloys, solder joint design, and soldering processes can be found in the Section "Solid-State Welding, Brazing, and Soldering Processes" in *Welding, Brazing, and Soldering*, Volume 6 of the *ASM Handbook*. In addition, the inspection of soldered joints used in electronic components and assemblies is covered in *Packaging*, Volume 1 of the *Electronic Materials Handbook*, published by ASM International.

There are three basic steps to achieving reliability of soldered joints, and each step requires some degree of inspection and quality control. These steps are material selection, joint design, and the soldering process.

Matching the flux to the base metal is an important consideration. The flux is a substance such as rosin or borax, applied to the surfaces to be joined just before or during soldering, that cleans the surfaces of oxides and facilitates their union. If an inadequate flux is used, the solder will not wet the metal properly, regardless of the time spent in making the connection. Correct solder alloy is another consideration. Not all solder alloys have the same properties, and it is important that the solder alloy match the application. A simple solderability test can determine whether the base metal, flux, and solder are compatible.

The joint design must be such that the joint has adequate current-carrying capacity (if an electrical connection) and strength. Without these properties, the joint may overheat or fail mechanically under stress. Joint designs that do not allow for visual inspection should be rejected at the design stage, and dimensional requirements should be established so that the inspector has fixed guides to follow. Adequate control must be maintained over the soldering procedures to eliminate variations in such conditions as soldering time, temperature, density of flux, and cleaning efficiency.

The inspection and testing of soldered joints should be considered in the final steps of the soldering operation. If not dictated by codes or specifications prepared by the user, the inspection and testing procedures should be selected by the manufacturer of the soldered joint, with due consideration given to the service conditions.

Workmanship samples are often prepared and used as guides to minimum levels of quality. Inspection and testing procedures are of two types: destructive and nondestructive.

Destructive Inspection

Destructive tests on soldered joints are usually performed on preproduction samples or test specimens to determine the suitability of a given solder, flux, or soldering procedure for a soldered joint of given mechanical properties. Preproduction samples or test specimens are made using the work metal, joint design, solder composition, flux, and soldering procedures specified for the proposed design. Short-time or long-time testing of soldered joints can be performed at elevated temperatures and under vibrating and static tensile loads as deemed necessary.

Difficulties may arise in testing the tensile strength of test specimens cut from thin sheets that are lap soldered. Sometimes during testing, because of the noncoincidence of the axes of symmetry in the lap-soldered halves of the test specimen, the seam area may assume an angle with the direction of the tensile stresses (Fig. 53). This leads to bending stresses that are difficult to determine. Shear strength values, determined according to the load divided by the lap area of the seam, do not reflect the true and intricate process of destruction of the soldered joint. Bending stresses do not occur in such tests if test specimens that are double lap soldered are used.

Fig. 53 Lap-soldered joints showing flat seam area before tensile testing, and bending that may occur during tensile testing

Soldered parts that require tightness in operation should be pressure tested. Low-pressure tests can be carried out with air, but high-pressure tests require the use of fluids. Because of possible damage, parts that have been pressure tested at or above the working pressure should be discarded.

Visual Inspection

Nearly all soldered joints are visually inspected for defects. The hand solderer visually inspects the joint as it is made and cleaned. The operator of a mass soldering machine usually gives at least a quick glance to each printed circuit board to ensure that the machine is still working properly. The only joints that need not be visually inspected are those for which a convenient nondestructive test is available.

A soldered joint surface should be shiny, smooth, and free of cracks, porosity, or holes. Ordinarily, no flux residues should remain. The transition from the edge of the solder surface to the exposed base metal should show a smooth profile. There should be no extraneous solder beyond the intended amount. Any area of base metal that has contacted the solder should show evidence of wetting.

The reasons for conditions different from those above include the heat sink effect of a nearby large conductive mass or a restraint of solder flow caused by the design of the joint. The inspector must question any condition that cannot be explained because it may indicate deeper problems. For example, slight dewetting around the pad of a printed circuit board is sometimes considered acceptable, but if the dewetting were to extend over the solder/land interface, the strength and reliability of the joint could be seriously impaired.

The degree to which any flaw is cause for rejection must be determined for each application. It is not possible to generalize. For example, some military specifications require that all holes on a soldered printed circuit board be filled with solder, while a commercial application, such as a small radio, would not require such perfection. The differences are often small, and good-quality joints are found in all types of applications.

Normally, inspection is facilitated by the use of a magnifying device that should provide no more than a 10× magnification factor, because too much magnification may make very minor flaws seem more important than they actually are. However, very small joints, such as in microelectronics, require additional magnification to bring the image up to "normal" size. Visual inspection of soldered joints requires training and experience for the inspectors. Training assistance, ranging from simple training aids up to full courses of instruction, is commercially available. Despite this requirement, no other method of testing is currently competitive with visual inspection for a wide range of soldered joints. Common discontinuities in soldered assemblies that are detectable by visual inspection are covered in the following sections.

Dewetting is a phenomenon in which solder flows over a surface and wets it, but before the solder solidifies, a change in the relative surface tension forces takes place so that the solder withdraws into ridges and globules similar to water on a greasy surface. The areas between solder globules retain the color of solder, but they have poor solderability, and this surface can be made to wet properly only with great effort, if at all. The exact mechanism of dewetting is not well understood, but dry abrasive cleaning that leaves particles imbedded in copper is one cause.

Nonwetting is more obvious than dewetting because, in most cases, the base metal retains its original color. Like dewetting, nonwetting is a major flaw because the solder joint is not continuous and is therefore weak. In most cases, nonwetting in very small amounts scattered across the surface can be tolerated. Typically, nonwetting can be traced to insufficient flux activity or inadequate time and/or temperature during soldering.

A flaw related to dewetting or nonwetting is the poor filling of capillary spaces, such as the holes on printed circuit boards. Nonwetting or dewetting may cause the poor fill, or excessive joint clearances may prevent joint completion. If the latter is the cause, the joint may still be acceptable, depending on the required soldering quality level.

Dull or rough solder surfaces can result from overheating or underheating. Overheating is not so damaging to the solder itself, but may damage surrounding heat-sensitive materials. Underheating produces poor contact of the solder with the base metal, but can probably be repaired. A dull, not necessarily rough, surface may also result from vibration or movement during solidification or from certain solder contaminants. Contamination is often inconsequential, but vibration could mean that a degree of weakness has been introduced into the joint structure.

Bridging. Bridges of solder spanning the space between solder joints cannot be tolerated, especially in electrical connections. Assuming that the spacing of the connections is adequate (a design parameter that depends on many factors), the most likely cause of bridging is contamination of the solder by an element that promotes oxides in the solder, such as excess cadmium or zinc.

A related phenomenon is icicling, which resembles incomplete bridges. These spikes of material attached to the joints are normally associated with wave or drag soldering. The same impurity that causes bridging can also cause icicles by interfering with the drainage of the solder as the printed circuit board is removed. Another possible cause is improper alignment of the path of the board when exiting the bath.

Porosity in the solder joint, if small and scattered, poses no threat to reliability. Large pores can significantly decrease the volume of solder in the joint area and therefore the strength of the joint. Pores that break the solder surface can trap corrosive materials or can extend down to the base metal, allowing local corrosion. Such gross porosity is formed when a bubble of air, flux vapor, or water vapor is trapped in the solidifying solder. In some cases, such defects can only be found through sectioning of the soldered joint, but usually there is some other evidence of a problem to alert the inspector.

Excessive Solder. Another discontinuity is excess solder in the joint areas, which may mask other discontinuities. Obviously, where visual inspection is the only possibility, any condition that interferes with the inspection cannot be tolerated.

Nondestructive Inspection **

For a few soldering applications, especially those for which the solder forms a fluid seal, pressure or vacuum testing can be used to check for leakage. The choice is usually determined by the intended application. For example, food cans that will be vacuum packed are tested by sealing and evacuating the can. The special test machine then monitors for any loss of vacuum. Vehicle radiators and other heat exchangers that operate under pressure are leak tested by creating an air pressure inside the part being tested while it is immersed in a water tank. The test pressure is normally selected to be at least as great as the pressure level to be encountered in use. Plumbing joints are usually checked visually for leaks by test operation of the system.

For large, flat areas, such as the mounting of photovoltaic cells for solar arrays, x-radiography has been used. Unfortunately, the design of the soldered joint rarely allows this test method.

New developments include acoustic emission, laser inspection techniques, and acoustic microscopy. Because acoustic emission requires slight deformation of the solder to generate a signal, there is some risk of damaging the joint during testing.

The laser inspection technique is most easily applied to cases in which many joints of the same geometry are to be tested. The basic concept of the technique is a burst of heat generated in the joint by the laser. The amount of heat absorbed is monitored and related to joint quality (Ref 8, 9). Figure 54(a) shows a cross section of a normal lap joint during laser beam heating. The surface-generated heat flows normally through the lead and into the underlying solder because of the intimate thermal contact. Figure 54(b) shows a heating curve taken during the laser pulse, which represents a normal amount of observed surface warming.

Fig. 54 Schematic of laser/thermal inspection of soldered joints. (a) Cross section of an acceptable lap joint during laser beam heating. (b) Heating curve taken during the laser pulse of acceptable joint. (c) Defective lap joint containing an air pocket. (d) Thermal signal of the defective joint. IC, integrated circuit. Source: Ref 9

A defective joint containing an air pocket beneath the lead is shown in Fig. 54(c). The trapping of heat in the lead is depicted by the compressed family of isothermal contours, resulting in a higher thermal signal, as shown in Fig. 54(d).

A composite of thermal signatures for a variety of acceptable and unacceptable solder joints is shown in Fig. 55. The unshaded area denotes a reference region in which acceptable thermal signals might fall, taking account of normal variation in solder mass, heat sinking, and surface quality. The signatures of defects would fall into the shaded areas, each having a finite extent because each defect type has varying degrees of severity.

Fig. 55 Typical thermal signatures for acceptable and defective soldered joints inspected by the laser beam heating technique. Source: Ref 9

In acoustic microscopy, magnified acoustic images of the elastic structure of the surface or interior of a solid are produced by passing high-frequency focused acoustic pulses through the material and displaying the received signals in image form as shades of gray (Ref 10). Usually, much higher frequencies are used than in other kinds of acoustic imaging. The acoustic pulses are focused directly, or the energy used to produce the pulses is focused into a very small region. When a small area of a specimen is scanned with a series of focused pulses and the transmitted or reflected signals are viewed on an imaging system (a television picture tube, a gray-scale recorder, or some other scanned display), the magnification of the resulting image is equal to the ratio of the diameter of the display to the diameter of the area scanned. At present, acoustic microscopy includes several methods for the formation of magnified acoustic images. The three discussed in the article "Acoustic Microscopy" in this Volume are scanning acoustic microscopy, C-mode scanning acoustic microscopy, and scanning laser acoustic microscopy. Acoustic images can also be produced by C-scan ultrasonic imaging as described in the article "Ultrasonic Inspection" in this Volume. The following example demonstrates the use of combined x-ray inspection and acoustic microscopy for determining soldered joint integrity.

Example 3: Determination of Silicon-Solder Attachment Integrity.

Two [111] cut silicon wafers, 40 mm (1.5 in.) in diameter and 0.32 mm (0.0125 in.) thick, were vacuum soldered together. The solder foil was initially 25 μm (0.001 in.) thick before melting. The sample was fabricated to study silicon-solder integrity through the use of acoustic microscopy and x-ray shadow-graphs.

Sample Preparation. The sample was prepared in the following manner:

- A solder foil was placed between the two prepared silicon wafer surfaces. The assembly was placed in a vacuum apparatus, on a surface that could be heated electrically, with an axial load applied perpendicular to the plane of the wafers
- A vacuum was applied (~ 135 Pa, or 1 torr), the sample was heated, the solder melted, and then the assembly was cooled under vacuum. The x-ray image shown in Fig. 56(a) was taken at this step in the sample preparation. Figure 56(a) clearly shows a number of voids in the solder layer
- Because of the voids in the solder layer, the sample was reheated, this time in a dry nitrogen glove box, at atmospheric pressure. An additional x-ray image (Fig. 56b) indicated that the large voids had now been closed. This was possible at the modest pressure applied by the atmosphere because the voids contained only vacuum. However, an acoustic microscope image (Fig. 57), in addition to displaying grain structure and small voids, indicated that the solder still was not well attached and had probably never achieved good attachment over most of the initial solder foil area

Fig. 56 X-ray images of silicon-solder sample. (a) X-ray shadowgraph after initial solder bond in vacuum. Light-gray areas are voids in the solder. (b) X-ray shadowgraph of sample after reheating at atmospheric pressure. Note that most of the major voids have been closed. Courtesy of Robert S. Gilmore, General Electric Research and Development Center

Fig. 57 Acoustic micrograph made with a 50-MHz transducer focused through the silicon on the solder bond. The focused beam diameter is approximately $75\ \mu\text{m}$ (0.003 in.). Courtesy of Robert S. Gilmore, General Electric Research and Development Center

Inspection Procedure/Defect Analysis. The microfocus x-ray images were made at 100 kV with Polaroid film. The wafer and film were placed at a source-to-target distance of approximately 750 mm (30 in.).

The acoustic micrographs were made with an ultrasonic microscope using a 6 mm (0.25 in.) diam 50-MHz transducer with a focal length of 13 mm (0.5 in.) in water. Figure 57 was made by focusing the ultrasonic beam on the solder layer and scanning it at a pulse-to-pulse and line-to-line spacing of approximately 25 μm (0.001 in.). The gray-scale display is of the amplitude of the ultrasonic echo from the solder layer. The solder grains are imaged because their elastic anisotropy results in a different echo amplitude at the silicon/solder interface.

Conclusions. X-ray images clearly indicated voids where the pores contained substantial volume. However, because the x-rays produced no difference in density, they could not detect a lack of attachment between a solder layer of uniform thickness and the two wafers, where the lack of attachment was not accompanied by a pore volume. Small voids also showed poor detectability when they resulted in an intensity change of less than a shade of gray (-3 dB) in the x-ray transmission shadowgraph image.

The acoustic image (Fig. 57) clearly displays the attachment integrity of the final assembly as well as evidence of the stages in its preparation. The grain size in the well-attached portion of the solder layer is clearly displayed, as are the voids in this layer. The outlines of the original x-ray detected voids are indicated as well as the grain structure of the solder now filling these areas and the location of a few small voids still remaining. The lack of attachment over large regions of the wafer is indicated, and the fabricators of the sample verified that these regions clearly outline the original solder foil area. It seems reasonable to conclude that a combination of x-ray and acoustic evaluations could supply the most information on silicon-solder attachment, but for this specific geometry the acoustic images provided the most information.

Cracked Soldered Joints

Cracks occur in soldered joints for a number of reasons, and each type of crack may have a distinctive appearance. Among the causes of cracks in soldered joints are excessive mechanical loads, differential thermal expansion, foreign material, improper joint clearances, and intermetallic compound layers.

Excessive mechanical loads produce fractures that are characterized by the nature of the applied stress. As the load increases, the cracks become wider and deeper until fracture occurs. If the load on the base metal creates excessive tensile shear loading on the solder, the specimen will exhibit a typical cup-and-cone fracture with the angle of the cone approximately 45° to the applied load, as shown in Fig. 58(a). If the solder is overloaded in compressive shear, the fracture surface will be parallel to the applied load, as shown in Fig. 58(b). If the joint was of questionable strength before soldering, the inspection process itself may overload the solder and produce cracks.

Fig. 58 Fracture mode (a) in excessive tensile shear load of solder; cup-and-cone fracture line is at 45° to the tensile axis. (b) Fracture mode in excessive compressive shear load of solder; fracture surface is cylindrical and is parallel to the load axis.

Differential thermal expansion can cause solder cracks; these generally consist of a series of closely spaced hairline cracks. To eliminate this type of crack, design specifications concerning the choice of base metals, solder alloys, and amount of thermal cycling permitted should be revised.

Foreign material such as flux inclusions and gas bubbles can act as nucleation sites for cracks. Small, random cracks frequently radiate from the inclusion or bubble to the outer surface. The remedy lies in more care and skill in the soldering operation.

Improper joint clearances may prevent proper flow of molten solder and thus create a joint of subnormal strength, which is vulnerable to cracks. A clearance of less than 75 μm (0.003 in.) may result in flux entrapment, poor solder penetration, and voids. Small, random cracks may radiate from the voids to the outer surface. On the other hand, a clearance greater than 125 μm (0.005 in.) may impair the capillary flow of molten solder and also form voids. In this situation, cracks may form parallel to the joint at the point of incomplete fill. The most satisfactory capillary flow of solder is achieved with joint clearances between 75 and 125 μm (0.003 and 0.005 in.).

Intermetallic compound layers formed in the solder may cause embrittlement and subsequent cracking. Generally, the cracks are parallel to the surface of the part and open to the surface for a comparatively long distance. They may result from high temperature, or excessive time at temperature, during the soldering operation, or from the alloy combinations chosen for the joint. In high-reliability systems, for example, the connections are frequently gold plated before soldering to ensure good corrosion resistance and adequate solderability. However, if the gold finish is only partly dissolved in the solder, a layered structure may form that is very susceptible to cracking. This structure consists of layers of gold plate, of the AuSn_4 intermetallic compound, and of solder. It is the interface between the soft gold and the hard AuSn_4 that initiates the cracks. A printed circuit board connection with a crack between the gold plate and the AuSn_4 is shown in Fig. 59.

Fig. 59 Section through a cracked soldered connection on a printed circuit board. At A is the tin-lead solder with a thin layer of the intermetallic compound AuSn_4 (B) on its underface. C is the crack that opened at the interface between the AuSn_4 and a layer of gold plate at D. E is a layer of nickel plating over two layers of copper plate (F) on the circuit board (G). 500 \times

Corrosion of Soldered Joints

Either galvanic or chemical corrosion can attack a soldered joint to a degree that may severely weaken its structural integrity or completely destroy it. In electrical connections, the occurrence of corrosion in a soldered joint may either increase the circuit resistance by impairment of contact or cause current leakage through surface deposits of conductive corrosion products. Problems in relay contacts can arise because of deposits of nonconductive corrosion products on conductive surfaces. Although the corrosion products due to many causes of corrosion are visible as white or green powder or dust around the soldered joint, corrosion due to flux residues will not necessarily result in discernible corrosion products.

Galvanic corrosion will occur when a sufficiently large difference in electromotive force exists between base metals or between solder and base metal, provided that an electrolyte is present on the soldered joint.

Chemical corrosion of soldered joints is frequently caused by inadequate removal of corrosive flux residues left from the soldering operation. Other causes of chemical corrosion include residual plating or etching solutions and contamination from packaging materials, handling procedures (including human perspiration), and environmental conditions. Additional information on the corrosion characteristics of soldering alloys and soldered assemblies is available in *Corrosion*, Volume 13 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*.

Cleanliness in Soldered Joints

It is important that traces of flux or flux residues be removed during postsoldering cleaning procedures. In addition, many solder operations are by nature contributors of small solder droplets. These small metallic particles can eventually be dislodged in the assembly and can cause short circuits and other undesirable side effects. When an assembly is improperly cleaned after soldering or fluxes are not removed, visual inspection is physically hampered. Cleanliness is therefore one of the items that should be specified in any proper procedure for the inspection of soldered joints.

Developments in high-reliability low-current circuitry (especially printed circuits) have emphasized the importance of cleanliness of electronic assemblies because of the danger of corrosion. Corrosion damage to conductors can increase circuit resistance, and high resistance is undesirable. Corrosion can also cause physical failure of the conductors by weakening and embrittlement. In addition, corrosion products themselves can cause current leakage. Current leakages are particularly bad because they are not consistent; humidity changes in the atmosphere cause variations in and sometimes intermittent occurrences of current leakage. Corrosion products also can cause contamination throughout the whole system in the form of nonconductive deposits on mechanical contacts and relay surfaces. Corrosion is definitely a problem, but corrosion is not always caused by fluxes. Additional information on the sources of corrosion in electronic components is available in the articles "Corrosion in the Electronics Industry" and "Case Histories and Failures of Electronics and Communications Equipment" in *Corrosion*, Volume 13 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*.

Cleanliness is easily checked after the proper cleaning procedures are followed. The danger to the assembly stems from the presence of ionizable materials, mostly chlorides. The easiest and most thorough check is done with a conductivity cell and distilled and demineralized water, either leaching the ionizable materials off the surfaces in premeasured amounts of water or submerging the whole assembly into a container of the water and measuring the resistivity of the water. This indicates the presence of ionizable materials. However, because chlorides are the major contributors in the corrosion mechanism and are the most abundant form of ionic contamination on the assembly, standardized, simple silver nitrate tests can be used to establish the presence of chlorides.

Cleanliness after soldering is important because soldering is usually the last step in a long process of assembly. However, precautions must be taken to prevent recontamination of the surfaces; otherwise, the purpose of cleanliness and of the check for corrosion products in the final inspection is defeated.

Nondestructive Inspection of Adhesive-Bonded Joints*

Donald J. Hagemaiier, Douglas Aircraft Company, McDonnell Douglas Corporation

Introduction

ADHESIVE-BONDED JOINTS in which adhesives are used to join and reinforce materials (Fig. 1), are extensively used in aircraft components and assemblies where structural integrity is critical. Figures 2 and 3 show typical adhesive-bonded joints used in aircraft structural assemblies. However, the structural components are not limited to aircraft applications, but can be translated to commercial and consumer product applications as well. In terms of production cost, ability to accommodate manufacturing tolerances and component complexity, facility and tooling requirements, reliability, and repairability, adhesive bonding is very competitive when compared to both co-cure and mechanical fastener joining methods.

Variables such as voids (lack of bond), inclusions, or variations in glue line thickness are present in adhesive-bonded joints and will affect joint strength. This article addresses the problem of how to inspect bonded assemblies so that all discrepancies are identified. Once the flaws are located, engineering judgment and analysis can determine if adequate strength exists or if the parts need to be reworked or scrapped. When very large and costly assemblies have been bonded, the importance of good non-destructive inspections is fully appreciated.

This article describes several techniques and presents drawbacks and limitations where they exist. No single method or procedure can locate every flaw, so it is important for personnel to be aware of the available techniques and their limitations. Bonded assemblies are inspected immediately after the adhesive cure cycle, after the parts have been cleaned and removed from the manufacturing jigs or fixtures. The next important time for inspection is after the assemblies have been in use and the condition of the parts is known. It is necessary to determine if new delaminations have occurred or if any metal cracks have developed. Inspection in the field requires the instruments to be easily transported and to be used in confined places.

The commonly used terms describe what is to be done. For example, nondestructive testing (NDT) comprises the testing principles methodology, nondestructive inspection (NDI) involves inspection to meet an established specification or procedure, and nondestructive evaluation (NDE) is the actual examination of materials, components, and assemblies to define and classify anomalies or discontinuities in terms of size, shape, type, and location. This article specifically addresses the three terms as they apply to adhesive-bonded joints within structures.

Inspection reference standards must be developed for each instrument, and the standards must be made available to and used by inspectors to standardize their equipment and to permit them to detect anomalies that will indicate a flaw. Inspectors must also be familiar with the internal details of the assembly being inspected so that they can distinguish between flaws and legitimate structural details. For example, how many layers of metal were bonded at any one spot?

Nondestructive Inspection of Adhesive-Bonded Joints*

Donald J. Hagemaiier, Douglas Aircraft Company, McDonnell Douglas Corporation

Description of Defects

There are a wide variety of flaws or discontinuities that can occur in adhesive-bonded structures. Table 1 lists possible generic flaw types and their producing mechanisms. Metal-to-metal voids or unbonds are the most frequently occurring rejectable flaws, as indicated in Table 2.

Table 1 Generic flaw types and flaw-producing mechanisms

Flaw-producing mechanism	Generic flaw type				
	Metal-to-metal	Metal-to-core	Core	Surface	Adhesive
Disbonds, internal	X				
Disbonds, part edge	X	X			
Disbonds, high core	X				
Porosity	X	X	X		X
Unremoved protective release film from adhesive	X	X			
Foam adhesive in film adhesive bond line	X	X			
Cut adhesive	X	X			X
Adhesive gaps	X	X			
Missing adhesive	X	X	X		
Weak bonds	X	X	X		

Extra layers of film adhesive	X	X			
Foreign objects	X	X	X		X
Double drilled or irregular holes	X			X	
Disbonds, low core		X			
Void or gap, chemical milled land		X			
Void or gap, doublers		X			
Missing fillets		X			
Void, closure-to-core		X			
High-density inclusions (chips, etc.)	X	X			X
Voids, foam joint		X	X		
Disbond, shear ties	X	X			
Lack of sealant at fasteners		X			
Thick foam adhesive		X			
Broken fasteners	X	X

Table 2 Frequency of rejectable flaws in adhesive-bonded assemblies

Defect	Number of defects	Percentage of total
Metal-to-metal voids and disbonds	378	74
Skin-to-core voids and disbonds	19	3
Gap in core-to-closure bond	9	2
Lack of foaming adhesive or voids in foaming adhesive	22	4
Difference in core density	6	2
Lack of fillets	1	1
Crushed or missing core	32	6
Short core	40	8
Total	507	100

Interface defects are the result of errors made during the pretreatment cycle of the adherends prior to the actual bonding process. In practice, pretreatment flaws are reduced by careful process control and by adherence to specification requirements and inspection before proceeding with the bond cycle. Controls generally include the waterbreak test and measurement of the anodic layer and primer thickness. Interface defects can be caused by improper or inadequate degreasing, deoxidizing, anodizing, drying, damage to the anodizing layer, or excessive primer thickness.

Interface defects are generally not detectable by state-of-the-art NDT methods. Therefore, test specimens are processed along with production parts and sent to the laboratory for evaluation. Applicable wedge crack specimens, lap shear specimens, or honeycomb flatwise tension specimens are fabricated and tested to determine if the process meets specification requirements before the bonding cycle starts.

Considerable effort at Fokker in the Netherlands led to the important discovery that the ideal oxide configuration for adhesion on aluminum alloys can be detected by inspection with an electron microscope at suitable magnification (Ref 2, 3, 4). To inspect with the electron microscope, a piece of the structure must be removed. As a consequence, the electron microscope became a useful tool for adhesion quality control. Another physical parameter that was used as a basis for the NDT of surfaces for the ability to bond was contact potential, which is measured by a proprietary method developed by Fokker known as a contamination tester (Ref 3, 5). This instrument is based on Kelvin's dynamic-condenser method but avoids the disturbances usually associated with it. There is sufficient evidence that the contamination tester is able to detect nondestructively the absence of the optimum oxide configuration arising from incomplete anodizing and/or subsequent contamination (Ref 4).

More recently, Couchman *et al.* (Ref 6) at General Dynamics developed an adhesive bond strength classifier algorithm that can be used to build an adhesive bond strength tester. Lap shear specimens were fabricated using Reliabond 398 adhesive. The test specimens include:

- A control set with optimum bond strength
- An undercured set
- A weak bond produced by an unetched surface
- A thin-bond adhesive that was cured without a carrier

The weakest bond was observed to fail at 725 kPa (105 psi), while the strongest held to 15.7 MPa (2.27 ksi). Tabulated results showed the following:

- *Undercured set:* 725 to 6410 kPa (105 to 930 psi)
- *Unetched surface set:* 5.79 to 7.58 MPa (0.840 to 1.10 ksi)
- *Control set:* 13.4 to 14.8 MPa (1.94 to 2.15 ksi)
- *Thin adhesive set:* 14.1 to 15.6 MPa (2.05 to 2.27 ksi)

The accept/reject value was set at 13.1 MPa (1.90 ksi), and all specimens were classified correctly. The important factor is that an interface defect (unetched surface), which results in poor adhesion, was detected.

Defects within the cured adhesive layer can be one or more of the following:

- Undercured or overcured adhesive
- Thick adhesive resulting in porosity or voids due to improper bonding pressure or part fit-up
- Frothy fillets and porous adhesive caused by too fast a heat-up rate
- Loss of long-term durability due to excessive moisture in the adhesive prior to curing

In normal cases, the curing time is very easily controlled. The curing temperature and temperature rate are controlled by proper positioning of the thermocouples on the panel and by regulating the heat-up rate.

Thick glue lines occur in a bonded assembly due to inadequate mating of the facing sheets or blocked fixing rivets, and they result mostly in porosity and voids. However, a thick glue line made with added layers of adhesive is usually free of

porosity. Porosity has a significant effect on the strength of the adhesive, with higher porosity related to a greater loss in strength and a void condition resulting in no strength. These defects occur quite frequently (Table 2). Porosity can also be caused by the inability of volatiles to escape from the joint, especially in large-area bond lines. Excessive moisture in the adhesive prior to curing can be prevented by controlling the humidity of the lay-up room. The entrapped moisture, after curing, cannot be detected by NDT methods unless it results in porosity.

Other defects that occur during fabrication can include:

- No adhesive film
- Protective film left on adhesive
- Foreign objects (inclusions)

In practice, these conditions must be prevented by process control and training of the personnel engaged in the bonding operation. The first two conditions occur infrequently. Shavings, chips, wires, and so on, can result in porosity or voids. Honeycomb core assemblies have been found with all types of foreign material.

Metal-To-Metal Defects

Voids. A void is any area that should contain, but does not contain, adhesive. Voids are found in a variety of shapes and sizes and are usually at random locations within the bond line. Voids are generally surrounded by porosity if caused by a thick bond line and may be surrounded by solid adhesive if caused by entrapped gas from volatiles.

Unbonds or Disbonds. Areas where the adhesive attaches to only one adherend are termed unbonds. Unbonds can be caused by inadequate surface preparation, contamination, or improperly applied pressure. Because both adherends are not bonded, the condition is similar to a void and has no strength. Unbonds or disbonds are generally detectable by ultrasonic or sonic methods.

Porosity. Many adhesive bond lines have some degree of porosity, which may be either dispersed or localized. The frequency and/or severity of porosity is random from one assembly to the next. Porosity is defined as a group of small voids clustered together or in lines. The neutron radiograph shown in Fig. 4(a) confirms the presence of porosity in the bond lines visible to the eye in Fig. 4(b). Porosity is detected equally well using conventional radiography or neutron radiography (Fig. 5). Scattered linear and dendritic porosity is usually found in adhesives supported with a matte carrier. Linear porosity generally occurs near the outer edge of a bonded assembly and in many cases forms a porous frame around a bonded laminate. Porosity is usually caused by trapped volatiles and is also associated with thick (single-layer adhesive) bond lines that did not have sufficient pressure applied during the cure cycle. The reduced bond strength in these porous areas is directly related to its density frequency and/or severity.

Fig. 4 Neutron radiograph (a) and visual confirmation (b) of porosity in an adhesive-bonded joint

Fig. 5 Porosity in an adhesive-bonded joint. (a) X-ray radiograph. (b) Neutron radiograph

Porous or Frothy Fillets. This condition results from too high a heat-up rate during curing. The volatiles are driven out of the adhesive too rapidly, causing bubbling and a porous bond line, which is distinguished by the frothy fillets. This defect is visually detectable and should also be seen in the test specimens processed within the production parts.

Lack of Fillets. Visual inspection of a bonded laminate can reveal areas where the adhesive did not form a fillet along the edge of the bonded adherends or sheets. In long, narrow joints, a lack of fillet on both sides generally indicates a complete void. This defect is considered serious because the high stresses near the edges of a bond joint can cause a cracked adhesive layer due to shear or peel forces. A feeler gage can be used to determine the depth of the defect into the joint. If the gap is too tight for a feeler gage, ultrasonic or radiographic techniques can be used to determine the depth of the edge void.

Fractured or Gouged Fillets. These defects are detected visually. Cracked fillets are usually caused by dropping or flexing the bond assembly. Gouges are usually made with tools such as drills or by impact with a sharp object. Fractured and gouged bond lines are considered serious for the reasons stated earlier for lack of fillets.

Adhesive Flash. Unless precautions are taken, adhesive will flow out of the joint and form fillets plus additional adhesive flow on mating surfaces. Although the condition is not classified as a defect, it is considered unacceptable if it interferes with ultrasonic inspection at the edges of the bonded joint where stresses are highest.

Burned Adhesive. The adhesive may be burned during drilling operations or when bonded assemblies are cut with a band saw. The burned adhesive is essentially overcured, causing it to become brittle and to separate from the adherend. Also, the cohesive strength of the burned adhesive is drastically reduced. Figure 6 shows burned adhesive around hole 9 caused by improper drilling, as well as bond delamination along the edge of the panel adjacent to holes 16 through 20

caused by band sawing. Improper drill speed or feed coupled with improper cooling can cause these types of defects. The burned adhesive around hole 9 in Fig. 6 is detectable by ultrasonic C-scan recording methods (Fig. 7).

Fig. 6 Examples of burned adhesive

Fig. 7 Ultrasonic C-scan recording of right side of Fig. 6

Adherend Defects

Adherend defects can be detected visually and do not include the processing procedures.

Fractures (Cracks). Cracks in the adherend, whatever the cause, are not acceptable.

Double-Drilled or Irregular Holes. Some bonded assemblies may contain fastener holes. When holes are drilled more than once, have irregular shapes, or are formed with improper tools, they are considered defects. The load-carrying capacity of the fasteners is unevenly distributed to the adherends, resulting in high local stresses that may cause fracture during service.

Dents, Dings, and Wrinkles. These defects are serious only when extensive in nature, as defined by applicable acceptance criteria or specifications. They are most detrimental close to, or at, a bond joint. Dents are usually caused by impact with blunt tools or other objects and are usually rounded depressions. Dings result from impact with sharp objects or when an assembly is bumped at the edge. Dents or dings may cause bond line or adherend fractures. Wrinkles are bands of distorted adherends and are usually unimportant.

Scratches and Gouges. A scratch is a long, narrow mark in the adherend caused by a sharp object. Deep scratches are usually unacceptable, because they can create a stress raiser which may generate a metal crack during service. On the other hand, gouges are blunt linear indentations in the adherend surface. Deep gouges, like scratches, are generally unacceptable.

Honeycomb Sandwich Defects

The most prominent defects found or generated in honeycomb sandwich assemblies are summarized in Table 1. Adhesion and/or cohesion defects may also occur in bonded honeycomb sandwich assemblies. The metal-to-metal closure areas for honeycomb panels may exhibit the types of defects discussed in the preceding section. In addition, sandwich assemblies can have defects in the honeycomb core, between the core and skins, between core and closure, at chemically milled steps, and in core splices. These bond areas are shown in Fig. 8 for a typical honeycomb assembly.

Fig. 8 Typical configuration of bonded honeycomb assembly. (a) Trailing edge. (b) Leading edge

Water in Core Cells. Upon completion of the bonded assembly, some manufacturers perform a hot-water leak test to determine if the assembly is leakproof. If the assembly emits bubbles during the leak test, the area is marked and subsequently repaired. To ensure that all bonded areas are inspected and that no water remains trapped in the assembly, it is then radiographed. This is important because water can turn into ice during operational service and rupture the cells, or it can initiate corrosion on the skin or core. Water in the core can be detected radiographically when the cells are filled to at least 10% of the core height. Also, x-ray detection sensitivity is dependent on the sandwich skin thickness and radiographic technique. An additional problem is the ability to determine whether the suspect area has excessive adhesive, filler, or water. Water images usually have the same film density from cell to cell or for a group of cells, while adhesive or filler images may vary in film density within the cells or show indications of porosity. A radiographic positive print of moisture in honeycomb is shown in Fig. 9.

Fig. 9 Positive print from x-ray negative showing water intrusion into honeycomb cells

Crushed Core. A crushed honeycomb core may be associated with a dent in the skin or may be caused by excessive bonding pressure on thick core sections. Crushing of the core greatly diminishes its ability to support the facing sheets. Figure 10 shows an x-ray positive print of crushed core. Generally, crushed core is most easily detected with angled x-ray exposures. Crushed core is defined as localized buckling of the cell walls at either face sheet, when associated with the halo effect on a radiograph. On the other hand, for wrinkled core, the cell walls are slightly buckled or corrugated. Radiographically, the condition appears as parallel lines in the cell walls. A wrinkled core is generally acceptable.

Fig. 10 Positive print from x-ray negative showing crushed honeycomb core

Condensed core occurs when the edge of the core is compressed laterally. Lateral compression may result from bumping the edge of the core during handling or lay-up, or slippage of detailed parts during bonding. The condition occurs most often near honeycomb edge closures. Figure 11 shows a positive radiograph of various degrees of condensed core.

Fig. 11 Two x-ray positive radiographs showing various degrees of condensed core

Node separation results when the foil ribbons are separated at their connecting points or nodes, as shown schematically in Fig. 12 and in the photograph in Fig. 13. Node separation usually occurs during core fabrication. It may also result from pressure buildup in cells as a result of vacuum bag leaks or failure, which allows the pressurizing gas to enter the assembly and core cells.

Fig. 12 Examples of honeycomb core separation. (a) Joined and solid nodes. (b) Node separation

Fig. 13 Radiograph illustration of node separation

Blown core occurs as a result of a vacuum bag leak or because of a sudden change in pressure during the bonding cycle. The pressure change produces a side loading on the cell walls that can either distort the cell walls or break the node bonds. Radiographically, this is indicated as:

- Single-cell damage, usually appearing as round or elliptical cell walls with partial node separation
- Multicell damage, usually appearing as a curved wave front of core ribbons that are compressed together

The blown core condition is most likely to occur at the edge of the assembly in an area close to the external surface where the greatest effect of sudden change in pressure occurs. This condition is most prevalent whenever there are leak paths, such as gaps in the closure ribs to accommodate fasteners, or chemically milled steps in the skin where the core may not fit properly. When associated with skin-to-core unbonds, the condition is detectable by pulse-echo and through transmission ultrasonic techniques. The condition is readily detectable by radiography when the x-ray beam centerline is parallel to the core cell walls, as shown in Fig. 14.

Fig. 14 Radiographic illustration of a blown core

Voids in Foam Adhesive Joints. Defects in core-to-closure, core-to-core splice, core-to-trailing edge fitting, and chemically milled steps (Fig. 8) in foam adhesive joints can result from the following conditions:

- The foam adhesive can slump or fall, leaving a void between the core and the face skins. This particular condition is most readily detected by ultrasonics
- The core edge dimension may be cut undersize and the foam does not expand uniformly to fill the gap between the closure and the core
- The foaming adhesive can fail to expand and surround the core tangs, as illustrated in Fig. 15

Fig. 15 Positive print from x-ray radiograph of foaming adhesive at core splice. (a) Lack of or unacceptable foaming at core splice. (b) Acceptable foaming at core splice

Protective Film Left on Adhesive. Protective films are usually given a bright color so that they can be seen and removed from the adhesive before bonding. If they remain on the adhesive, the adhesive is prevented from contacting one of the adherends. This condition is very difficult to detect by ultrasonic techniques and x-ray radiography, with which it would appear as a mottled condition. It generally produces porosity, especially at the perimeter, which aids in its detection.

Metal-to-Metal Defects. The most prominent defects are voids and porosity. Disbonds can occur under the following conditions:

- When the core is slightly higher than a closure member
- Lack of applied pressure from tooling
- Entrapped volatiles in the bond joint prior to cure
- Excessive moisture in the adhesive prior to cure
- Contaminated honeycomb core

Voids and porosity are detectable by low-kilovoltage (15 to 50 kV) x-ray techniques using a beryllium-window x-ray tube, by thermal neutron radiography, and by ultrasonic C-scan techniques employing small-diameter or focused search units operating at 5 to 10 MHz. If the flaw is the result of insufficient pressure, the adhesive will be porous, as shown in Fig. 4 and 5. The lower the kilovoltage and/or the thicker or denser the adhesive, the higher the resolution of the flaw image. In general, the flaw size detectable by radiography is smaller than that detected by ultrasonics. Also, some adhesives, such as AF-55 and FM-400, are x-ray opaque, which yields a much higher contrast among voids, porosity, and solid adhesive (Fig. 16). Disbonds (separation between adhesive and adherend) are best detected by ultrasonic techniques.

Fig. 16 Positive print from neutron radiograph showing void and porosity in an adhesive bond line. Two 13 mm ($\frac{1}{2}$ in.) thick aluminum adherends bonded with EA 9628 adhesive are shown; AF-55 adhesive bond would have yielded similar results with x-ray radiography.

One of the most important types of voids in honeycomb assemblies is the leakage-type void, which is oriented normal to the metal-to-metal bond line and penetrates to the core. Moisture can penetrate such a void during operational service and cause corrosion or ice damage to the core. This type of void is illustrated in Fig. 17(a) and 17(b).

Fig. 17 Schematics of leakage-type void and foam intrusion in metal-to-metal joints. (a) Leakage-type void, and foam intrusion into adhesive layer caused by excessive gap between extrusion and skins. (b) Leakage-type void. (c) Foam intrusion into adhesive

Foam Intrusion. Another type of defect that can cause problems in radiography is foam intrusion into a metal-to-metal joint near a closure. This type of flaw is illustrated in Fig. 17(a) and 17(c). Ultrasonically, it will appear bonded; therefore, ultrasonics cannot confirm the radiographic findings. Because this may or may not be a defect, it must be determined by engineering analysis.

Skin-to-Core Voids at Edges of Chemically Milled Steps or Doublers. This condition occurs when the adhesive fails to bridge the gap at the edges of chemically milled or laminated steps or doublers (Fig. 8). This is detected radiographically as a dark line or an elliptically shaped dark image. Ultrasonically, it will appear as a linear void along the chemically milled step position.

Missing Fillets. As pressure is applied during the bonding cycle, adhesive fillets are formed at the edges of each honeycomb cell. Fillets will not be formed if pressure is not maintained. If the adhesive is x-ray opaque, this condition is readily detected by directing the radiation at an angle of approximately 30° with respect to the centerline of the core or closure web. If the adhesive is not x-ray opaque, then ultrasonic, eddy sonic, and tap tests can be used to locate the area having unbonded cells. Ultrasonic C-scan can be used to record skin-to-adhesive and adhesive-to-core voids. Adhesive-to-core voids are more difficult to detect than skin-to-adhesive voids.

Short core can exist if the core edges are cut shorter than the assembly into which it will be placed and bonded. It is detectable by x-ray radiography and is evident as core edges that do not tie into the closure via the foaming adhesive.

Foreign Objects. Honeycomb assemblies may contain foreign objects as a result of poor fabrication practices. Nuts, rivets, small fasteners, metal chips, and similar items can be left in the honeycomb cells before bonding or as a result of drilling operations for fastener installations near hinge points. These objects are easily detected by x-ray radiography. They are usually not detrimental if they can be potted in place with a room-temperature adhesive.

Repair Defects

All the flaws or defects defined previously for metal-to-metal or honeycomb sandwich assemblies can occur during salvage or repair of these components. Repairs must be of good quality in order to maintain the reliability of the bonded structure during continued service.

In-Service Defects

Most defects or flaws caused during service originate from impact damage, corrosion, and poor fabrication.

Impact Damage. Many bonded assemblies are made from thin materials and are susceptible to damage by impact. Damage can be caused by small arms projectiles, work stands, dropped tools, personnel walking on no-step assemblies, stones or other debris thrown by aircraft wheels, and similar damage. Impact imposes strain on the adhesive, causing it to crack or separate from the adherends. Impact can cause crushed honeycomb core, resulting in loss of strength. The crushed core can resonate during service and slowly degrade the adhesive by fatigue until it debonds from the adherend or until cracks occur adjacent to the skin-to-core fillets. Fortunately, impact damage will generally leave a mark in the surface of the part. These surface marks pinpoint or indicate possible subsurface damage, which can be evaluated by NDT inspections.

Corrosion can be found in all structural concepts. However, a good example of bonding excellence is the honeycomb acoustic panels for the DC-10 and 747 engine inlets. These applications are quite demanding because of the combination of sonic and ambient environment being introduced into the perforated sandwich structure. Stable oxide surface preparation is an essential part of the bond foundation. Improper surface preparation can result in an unstable oxide layer, which may allow the entry of moisture, delamination, and/or crevice corrosion (Fig. 18).

Fig. 18 Schematics illustrating the causes of adhesive delamination for a metal adherend. (a) Results of moisture entry in the unstable oxide. (b) Corrosion of cladding and base aluminum. A, adhesive primer system; B, oxide; C, alcladding; D, base aluminum

Moisture entry to the core of a honey-comb assembly eventually leads to corrosion of the core. This occurs when moisture moves along the bond line to the individual cells. Moisture moves more rapidly in an assembly if the core is perforated. Fortunately, this moisture problem is detectable by NDT inspection methods. Water is detectable by x-ray radiography or by acoustic emission testing with a hot-air gun or heat lamp to cause boiling or cavitation of the water (Ref 7, 8, 9). Core corrosion and subsequent core-to-skin delamination is detectable by a variety of NDT methods, such as x-ray, contact ultrasonic ringing, sonic bond testers, eddy sonic, tap test, and acoustic emission with a heat source.

Figure 19 shows a section from a commercial aircraft wing trailing edge that had moisture entry at the leading and trailing edges, resulting in bond line corrosion. The corrosion in this panel was detected by x-ray radiography, bond testers, tap test, neutron radiography (which looked much like Fig. 19), and acoustic emission using a heat source.

Fig. 19 Positive print from x-ray radiograph showing interface corrosion of an adhesive-bonded aluminum laminate

Poor Fabrication (Flaws or Weak Bonds). In-service failures can occur from weak bonds (adhesion failures) caused by poor surface preparation, unstable oxide failure, and corrosion of alcladding and base aluminum alloy (Fig. 18). Many tests show that the alclad on 7000-series aluminum sheet is very susceptible to corrosion attacks in the bond line and must be thoroughly tested before consideration for bonding operations. The 2000-series alclad aluminum alloys are not as susceptible to this condition. Both series of alloys with no alclad surface but with good surface preparation, adhesive, and corrosion-inhibiting primer will have no corrosion problems.

Another manufacturing condition that leads to adhesion failures is caused by improper cleaning of the honeycomb core prior to bonding. This condition results if glycol (which is often used to support the core when it is machined) is not completely removed prior to bonding. Incomplete removal of glycol will cause a weak bond to exist, and in-service stresses may cause a skin-to-core delamination. This condition is controlled by adding a fluorescent tracer to the glycol. After the core is machined and cleaned, it is inspected, using an ultraviolet (black) light, for any residual glycol prior to bonding.

Nondestructive Inspection of Adhesive-Bonded Joints*

Donald J. Hagemaiier, Douglas Aircraft Company, McDonnell Douglas Corporation

Applications and Limitations of NDT to Bonded Joints

A variety of NDT methods are available for inspection. Only the methods applicable to the inspection of bonded structures will be discussed in this section. All the methods or techniques presented can be used in fabrication inspections, while only a limited number are applicable to on-aircraft or in-service inspection. The following methods have proved to be the most successful in detecting flaws in bonded laminates and honeycomb assemblies.

Visual Inspection

All metal details must be inspected to ensure conformity with design. Before large assemblies are ready for bonding, the details are assembled in the bonding jig as though bonding were to occur. In place of the adhesive, a sheet of Verifilm is used. This material has nearly the same flow characteristics as the adhesive, but it is prevented from bonding by release film so that it will not stick to the details. The whole assembly is placed in an autoclave or press just as if it were being bonded. After the heat-pressure cycle, the parts are disassembled, and the Verifilm is inspected visually to determine if the pressure marks are uniform throughout. A uniform marking gives good assurance of proper pressure at the bond lines. All areas showing no pressure must be inspected and parts modified to obtain proper fit and pressure during the cure cycle. A poor showing on the Verifilm is cause to rerun the check.

When the details go through an anodize cycle, a visual check can be made for phosphoric acid anodize but not for other types of anodize. For visual verification of phosphoric anodize, the inspector looks through a polarizing filter at an angle of approximately 5 to 10° from parallel to the surface of the anodized part. The surface of the panel is well lighted by a fluorescent tube, and the inspector rotates the polarizing filter while observing the anodized surface. If the panel has been properly anodized, the inspector, viewing at an angle of 50 to 100° from the panel surface, will see a change in hues equivalent to the colors of the rainbow.

From the opened wedge crack specimen, the inspector looks at the failed surface to determine the type of failure. Areas of poor adhesion occur where the adhesive has separated from the substrate. This condition is manifested by variations in color and texture. A cohesive failure occurs through the adhesive and is uniform in color and texture.

After an assembly is bonded, it is inspected visually for scratches, gouges, dings, dents, or buckles. The adhesive flash and fillets can be inspected for cracks, voids, or unbonds at the edge. Feeler gages can then be used to determine the depth of the unbond at the edge. The in-service visual inspection of bonded joints can reveal cracked metal or adhesive fillets, delamination or debonding due to water intrusion or corrosion, impact or foreign object damage, and blisters, dents, or other mechanical damage.

Ultrasonic Inspection

A number of different types of ultrasonic inspection using pulsed ultrasound waves at 2.25 to 10 MHz can be applied to bonded structures. Following is a brief description of the various ultrasonic techniques being used to inspect bonded structures. Additional information is available in the article "Ultrasonic Inspection" in this Volume.

Contact Pulse Echo. In this technique, the ultrasonic beam is transmitted and received by a single search unit placed on one surface of the part (Fig. 20a). The sound is transmitted through the part, and reflections are obtained from voids at the bond line. If the bond joint is of good quality, the sound will pass through the joint and will be reflected from the opposite face, or back side. Bonded aircraft structure is usually composed of thin skins, which result in multiple back reflections on the CRT screen of the pulser/receiver. The appearance of multiple reflections on the CRT has prompted some inspectors to term this the ringing technique. When a void is present, the reflection pattern changes on the CRT and no ringing is seen. For bonded parts having skins of different thickness, inspection should be conducted from the thin skin side.

Fig. 20 Ultrasonic inspection techniques. (a) Contact pulse echo with a search unit combining a transmitter and receiver. (b) Contact through transmission. Transmitter search unit on top and receiving search unit on bottom. (c) Immersion pulse echo with search unit (transmitter/receiver) and part being inspected under water. (d) Immersion through transmission with both search units (transmitter and receiver) and part under water. (e) Immersion reflector plate. Same as (c) but search unit requires a reflector plate below the part being inspected

Contact through transmission (Fig. 20b) is useful for inspecting flat honeycomb panels and metal-to-metal joints. Special search-unit holding devices have been fabricated so that the test can be performed by one inspector. Such a device is used for inspecting the metal-to-metal closures of a bonded honeycomb panel. Longer and wider-spaced holders have been fabricated from tubing. The holding tool should be custom designed for the assembly being inspected. To perform the test, liquid couplant must be applied to both sides of the assembly.

Immersion Method. For this method, the assembly must be immersed in a tank of water, or water squirters must be used to act as a couplant for the ultrasonic beam. There are three fundamental techniques: pulse echo (Fig. 20c), through transmission (Fig. 20d), and reflector plate (Fig. 20e). Typical CRT displays for bonded and unbonded samples using these three immersion techniques are shown in Fig. 21. These techniques are applicable to bonded laminates and

honeycomb structures. The choice of technique is partially based on the thickness and configuration of the bonded assembly as well as physical size.

Fig. 21 Typical CRT C-scan displays obtained for both bonded and unbonded structures using three pulsed ultrasound techniques. (a) Pulse echo. (b) Through transmission. (c) Reflector plate

Bonded structures are generally inspected by the immersion method using a C-scan recorder. A C-scan recorder is an electrical device that accepts signals from the pulser-receiver and prints out a plan-view record of the part on a wet or dry facsimile paper recording (Fig. 22). To obtain the recording, the bonded panel is placed under water in a tank, and the ultrasonic search unit is automatically scanned over the part. The ultrasonic signals for bond-unbond conditions are determined from built-in defect reference standards. The signals are displayed on the pulser-receiver CRT screen, and the signal amplitude is used to operate the recording alarm after setting the electronic gate around the signal of interest (Fig. 23). Generally, high-amplitude signals will record, but low-amplitude signals will not record. The recording level is adjustable to select the desired signal amplitude. Figure 23 illustrates a typical ultrasonic C-scan recording system.

Fig. 22 Schematics of immersion ultrasonic C-scan (a) scanner motion and (b) plan-view record of C-scan recording on facsimile paper

Fig. 23 Ultrasonic C-scan immersion system. (a) The system consists of a large water tank (A) with side rails (B), which support the movable bridge (C). The search unit (D) is held at a proper distance above the part by the scanner arm (E), moves across the part, and is then indexed along the longitudinal axis. The visual pulser-receiver unit (F) is mounted on the bridge. A permanent record is made by the C-scan recorder (G). (b) Close-up of pulser-receiver on the right and a close-up of the CRT presentation on the left. A recording level (A) is set on the instrument. All signals above will record on the C-scan machine, and signals below will not show. Item B is an automatic recording gate associated with the mechanics of record making.

Ultrasonic immersion techniques, employing a C-scan recorder, are extensively used by aircraft manufacturers to inspect adhesive-bonded assemblies. The C-scan recordings provide a permanent record with information on the size, orientation, and location of defects in bonded assemblies. The C-scan systems are designed to inspect particular parts and therefore vary considerably in size and configuration. Computer-operated controls have been incorporated into some systems to control the scanning motions of the search units and to change instrument gain at changes of thickness in the assembly.

The through transmission and reflector plate techniques are easier to perform than the pulse-echo technique and are useful for producing C-scan recordings of test specimens and flat laminates. Special equipment is required for large panels, squirters for honeycomb panels that cannot be immersed, and contour followers for contoured parts.

Ultrasonic Inspection Limitations. The ultrasonic method suffers from destructive wave interference thickness. Adhesive thickness interference effects are most notable at the pinch-off zone near the edges of laminates bonded with

adhesive using a mat (nonwoven) carrier. Metal thickness interference effects (Fig. 24) are usually obtained from any laminate having a bonded tapered doubler. The problem with the interference effects is that they make the parts appear unbonded. The phenomenon is complex and will require further study before its effects can be eliminated.

Fig. 24 Reflector plate C-scan at 5 MHz of ultrasonic destructive interference effects due to varying adherend thickness

Ultrasonic bond test methods or neutron radiography is used to determine the acceptability of bonded assemblies yielding C-scan results showing interference effects (see the section "Ultrasonic Bond Testers" in this article). Figure 25 shows a through transmission C-scan of a bonded honeycomb assembly. The lead tape (generally used for radiography) attenuates the ultrasonic beam and is therefore used to simulate voids and also as an index or orientation marker to relate the location of flaws in the part to the C-scan recording. In the contact pulse-echo ultrasonic inspection of bonded laminates, inspection from the thin adherend side produces the best results.

Ultrasonic Bond Testers

A wide variety of ultrasonic bond testers have been developed over the past 20 years. As a consequence, this mode of bond inspection probably requires the most study because of the number of instruments available and the claims of the manufacturers. Various independent studies have been conducted in an attempt to clarify the situation (Ref 2, 3, 10, 11, 12, 13, 14, 15, 16, 17, 18, 19, 20). The results of these studies revealed that all the instruments are capable, in varying degrees, of determining the quality of the bond. None of the instruments is capable of establishing the adhesive quality of a bond that is defective as a result of:

- Poor surface preparation of the substrate
- Insufficient cure temperature
- Contamination of the adhesive or substrate prior to bonding

The conclusions indicate that ultrasonic bond test instruments are the most reliable and sensitive for detecting voids, porosity, thick adhesive, and corrosion at the bond line, and that they can be used to inspect metal-to-metal and honeycomb structures.

Instruments such as the Coinda Scope, Stub Meter (Ref 13, 14), Sonic Resonator (Ref 11), and Arvin Acoustic-Impact Tester (Ref 15) have not found general acceptance and are no longer on the market. Following is a short description of the ultrasonic bond testers currently being used to inspect adhesive-bonded assemblies.

The Fokker Bond Tester (Fig. 26) is based on the analysis of the dynamic characteristics of the mass-spring and dashpot system formed by the combination of the bonded assembly with a piezoelectric transducer having known mass and resonance characteristics. Changes in the viscoelastic properties of the adhesive layer are detected as variations in the resonance frequency and impedance of the system. The calibrated body acts as a transducer that can be driven at different frequencies. The dimensions of the transducer are chosen in relation to the total thickness of the metal sheet to be tested and to the required mode of resonance. The response of the total system, as shown by the impedance curve over the swept frequency band, is displayed on a CRT display (A scale) (Fig. 27), and the peak-to-peak amplitude of the curve is shown by a microammeter (B scale).

Fig. 26 Fokker bond tester

Fig. 27 Several typical Fokker bond tester readings for specific bond conditions. (a) Probe held in air. (b) Probe is on top of the upper adherend (no bonds) and is a calibration for unbond condition. (c) Probe placed on a single piece of metal as thick as combined parts being bonded and calibrated for ultimate quality. (d) Probe

placed on bonded joint with good-quality bond (no voids); high-strength bond. (e) Probe placed on bonded joint with porosity; low-strength bond

For inspecting metal-to-metal bonded joints, the probe containing the calibrated body is placed on top of a piece of sheet material with the same thickness as the upper sheet material of the bonded laminate. The central frequency of the oscillator is selected such that the lowest point of the impedance curve is in the center of the A scale. Simultaneously, the B scale is adjusted to 100 (Fig. 27). Calibration of the instrument on a nonbonded sheet ensures that, in all cases of a complete void, the peak position will return to the center of the A scale and that the B scale reading will be 100 (Fig. 28). The next calibration places the probe on a piece of metal sheet equivalent in thickness to all the metal sheets in the subject bonded laminate. The peak obtained in this test is the resonance frequency to be expected of an ideally bonded laminate (Fig. 27 and 28).

Fig. 28 Typical displays of Fokker bond tester A scale for various qualities of adhesive-bonded joints. (a) Central frequency, no strength. (b) Higher frequency, low strength. (c) Lower frequency, high strength

The quality of cohesion from any test can be accurately determined by comparing the instrument reading with established correlation curves. In practice, the acceptance limits are based on the load or stress requirements of the adhesive for each joint. The accuracy of the prediction of quality depends primarily on knowing the manufacturing variables and the accuracy of the nondestructive and destructive tests conducted in accordance with MIL-STD-860 (Ref 21). The destructive test for metal-to-metal joints uses the lap shear specimen and, for honeycomb panels, uses the tension specimen for bond strength correlations. Comparative tests by several investigators indicate the Fokker bond tester to be more reliable in quantitatively measuring bond strength as related to voids and porosity in the joint (Ref 2, 3, 5, 10, 16, 18, 22, 23). For the inspection of honeycomb, calibration is accomplished in the same manner except that the micrometer (B scale) on the instrument is used. The degree of quality is reflected on the B scale. Low-quality bonds will give a high B reading, and good-quality bonds will give a low B reading.

The Fokker bond tester has been successfully applied to a wide variety of bonded sandwich assemblies and overlap-type joints of various adherends, adhesive materials, and configurations. The method has proved suitable for joints having reasonably rigid adherends, including metallic and nonmetallic materials. Highly elastomeric or porous adherends attenuate ultrasonic response. The method is most sensitive to the properties of the adhesive and is particularly sensitive to voids, porosity, and incomplete wetting (unbond). Fokker tests readily detect:

- Voids in either adhesive or nonmetallic adherend materials
- Cracks and delaminations in adherends
- Unbonded, flawed, ruptured, unpliced, or crushed honeycomb core

Data indicate the test to be capable of measuring bond degradation caused by such factors as moisture, salt spray, corrosion, heat aging, weathering, and fatigue.

NDT-210 Bond Tester (Fig. 29). Sound waves from a resonant transducer are transmitted into, and received from, the bonded structure. Unbonds or voids in the structure alter the sound beam characteristics, which in turn affect the electroacoustic behavior (impedance) of the transducer. A frequency range extending from less than 100 Hz to more than 6 MHz is provided for maximum performance. The unit automatically adjusts to the resonant frequency of the probe. A precision automatic gain control oscillator maintains a constant voltage at all frequencies, eliminating the need for manual adjustment. Test response is displayed on a 114 mm ($4\frac{1}{2}$ in.) wide meter. The operator can set an adjustable alarm to trigger when the response exceeds a preset level.

Fig. 29 NDT-210 bond tester

Metallic, nonmetallic, or a combination of joints can be inspected for voids and unbonds. The joints can be adhesively bonded, brazed, or diffusion bonded.

The Shurtronics Mark I harmonic bond tester (Fig. 30), now identified as the Advanced Bond Evaluator, is a portable, low-frequency, eddy sonic instrument that uses a single transducer for the inspection of thin metal laminations and metal-to-honeycomb bonded structures. The instrument utilizes a coil that electromagnetically vibrates the metal face sheet. This coil induces a pulsed eddy current flow in a conductive material by an oscillating electromagnetic field in the probe. The alternating eddy current flow produces an accompanying alternating magnetic field in the part. The attraction of the magnetic fields causes acoustomechanical vibrations in the part. When a structural variation is encountered, the change in acoustic response is detected by a broadband receiving microphone located inside the eddy current probe.

Fig. 30 Shurtronics harmonic bond tester

An ultrasonic oscillator generates a 14- to 15-kHz electric signal in the probe coil, creating an oscillating electromagnetic field. The resulting acoustomechanical vibration in the testpiece is detected by a microphone with a bandwidth of 28 to 30 kHz. The microphone signal is filtered, amplified, and displayed on a microammeter. The instrument is calibrated to read just above zero for a condition of good bond and to read full scale for unbonds over 13 mm ($\frac{1}{2}$ in.) in diameter or larger. This method does not require a liquid couplant on the part surface. It is useful for the quick detection of unbonds in large-area bonded metal laminates, metal-to-nonmetal laminates, or honeycomb structures. It is highly effective for detecting skin-to-core unbonds or voids in acoustic-honeycomb panels utilizing perforated facing sheets. The sensitivity of the instrument decreases rapidly for skin thickness over 2.0 mm (0.080 in.) and near the edge of the part.

The Advanced Bond Evaluator (ABE) bond tester (Fig. 31) has the following improvements:

- *1% alarm accuracy:* Vernier control ensures test repeatability with zero hysteresis
- *Phase comparator:* Detects defects in nonmetallic composite materials and provides additional information on metallic structures
- *Portable operation:* Self-contained batteries and built-in recharger
- *Modular construction:* Plug-in circuit boards for fast field servicing and maintenance

Fig. 31 Advanced Bond Evaluator bond tester. Courtesy of M. Gehlen, UniWest/Shurtronics Corporation

The Sondicator is a pulsed transmit/receive ultrasonic portable instrument that is capable of operating in a very low (25 to 50 kHz) acoustic frequency range. The instrument operates within this range at a selected single frequency, obtained by manual tuning for best instrument performance. The model S-2 contains two meters and associated electronic circuitry, along with a test probe containing two Teflon-tipped transducers mounted approximately 19 mm ($\frac{3}{4}$ in.) apart. One transducer imparts vibration at 25 kHz into the surface. Vibrations travel laterally through the material to the other transducer. The second transducer detects the amplitude and phase relationship of the vibrating surface, directing the associated signals to the two meters of the test equipment. If the probe encounters a delaminated or unbounded area, it will in effect be introducing vibration into an area that is thinner than the bonded area. The amplitude of vibration will increase and the phase of vibration will shift as the thinner section vibrates more vigorously. The needles on the two meters will move toward each other.

The instrument is primarily used to detect delaminations of the bond or laminar-type voids in metal and nonmetal structures. The inspection can be performed from one face of the structure or by through transmission. It requires no liquid couplant. Multiple bond lines and part edges will reduce the sensitivity of the instrument. Because of the directionality of the sound from the transmitter to the receiver, the part must be scanned uniformly. The unit is capable of detecting defects 25 mm (1 in.) in diameter and larger in most materials. Metallic and nonmetallic materials can be inspected without changing probes. Audible and visible alarms are activated by received signals. The instrument can detect internal delaminations and voids in bonded wood, metal, plastic, hard rubber, honeycomb structures, Styrofoam, and composites. It can measure skin or face sheet thickness in composite structures as a change in amplitude or phase (Fig. 32).

(a)

(b)

Fig. 32 Variation of amplitude (a) and phase (b) as detected with a Sondicator

Bondascope 2100. The Bondascope (Fig. 33) is an advanced microprocessor-based device that operates on the principle of ultrasonic impedance analysis. This technique allows the total ultrasonic impedance vector for the material to be monitored as a flying dot on a scope display. With the center of the scope screen as the origin (reference), impedance phase changes are displayed circumferentially, while impedance amplitude changes are displayed radially. Thus, the position of the dot on the scope immediately reveals the phase and amplitude of the impedance of the material (Fig. 33a). Therefore, defects at different bond lines each possess a characteristic dot position on the scope display.

Fig. 33 Bondascope 2100. (a) Front view of unit showing CRT readout of bond line depths. (b) Unit used as a component in a PortaScan bond testing system. Courtesy of R.J. Botsco, NDT Instruments

With the addition of a 640-KB random access memory (RAM) portable computer having a 229 mm (9 in.) built-in color monitor, a high-speed plug-in data acquisition card (DAC), a software package, and a 1.4 to 1.8 kg (3 to 4 lb) scanner incorporating a ball-bearing gimbal probe holder, the Bondascope 2100 becomes an integral part of the PortaScan (portable ultrasonic color scan imaging) system that can be used for both C-scan imaging and set-up flying dot (impedance plane) imaging (Fig. 33b).

Figure 34 illustrates the typical Bondascope response to unbonds at different bond lines (depths) in a multilayered adhesive-bonded laminate. The instrument was calibrated so that the dot was in the center of the screen (origin) when the probe was placed on a well-bonded section of the laminate. The numbered dots represent the signals obtained when the probe was placed over regions having unbonds located at different respective bond line depths in the laminate. The dot labeled "air" is the signature obtained when the probe was off the sample. Thus, improper ultrasonic coupling into the material is quickly recognized.

Fig. 34 Bondascope ultrasonic impedance plane presentation for multilayer laminar. (a) Orientation of Bondascope display of the unbonds shown in (b). (b) Multilayer bonded laminate with unbonds located at 1, 2, and so on

A meter on the Bondascope, by means of selectable push buttons, can display the signal amplitude, phase, or the vertical resolved component of the amplitude. Through the use of a phase-rotator control, the signal response can be positioned so that nonrelevant signals are suppressed from the meter/alarm readings.

A keyboard push-button matrix allows the operator to digitally program calibration-sample reference dots on the scope display to aid in interpreting signals obtained during actual testing. This type of storage display not only facilitates operation and interpretation but also eliminates the confusing permanent streaks that would occur if a conventional storage scope were used to display the flying dot.

The Bondascope is suitable for inspecting metallic and nonmetallic bonded structures (multilayered laminates or honeycomb). Graphite-epoxy and other fiber-matrix composites can also be tested with this device.

The NovaScope is a sophisticated high-resolution, pulsed ultrasonic thickness gage with a digital readout and scope display for qualifying the echo pattern. It is primarily intended for either manual contact probe or focused immersion (squiter) applications for which the conventional digital-only readout gages are not suitable. This is the case for structures having complex, difficult-to-test shapes or whenever the product is in motion. The instrument has a variety of controls for optimizing the test response to the desired ultrasonic echo periods.

Figure 35 shows the resolving power of the instrument for gaging thin materials. In this case, the material is a steel sheet only 0.15 mm (0.006 in.) thick. The upper trace is the A-scan echo pattern, while the lower trace shows the thickness gate reading adjusted between two successive echoes from the thickness of 0.15 mm (0.006 in.). This instrument is useful for testing thin composite laminates for delaminations, for detecting corrosion in aircraft skins, and for bond line thickness gaging.

Fig. 35 Novascope CRT display of a 0.15 mm (0.006 in.) steel sheet. Upper trace: A-scan echo pattern. Lower trace: Thickness gate reading obtained from two successive echoes. Courtesy of R.T. Anderson, NDT Instruments

Ultrasonic and Bond Tester Method Sensitivity. The defect detection sensitivity of ultrasonic techniques with respect to defect size and location is highly dependent on the changing conditions of part complexity, number of bond lines, operator experience, and so on. Most instruments detect major defects most of the time, but in some cases special techniques and skills are needed to conduct a reliable inspection. Whenever possible, bonded structures should be inspected from opposite surfaces to detect small defects. In the ultrasonic bond test methods, different-size search units or probes are available. The smallest flaw that can be readily detected is of the order of one-half the diameter of the search unit or probe element.

Test Frequency. The higher the test frequency, the smaller the flaw that can be detected. Ultrasonic testing at 5 or 2.25 MHz will detect smaller flaws than can be detected with the Sondicator (25 to 50 kHz) and the harmonic bond tester (15 kHz). With multiple bond lines in a structure, smaller flaws become progressively more difficult to detect from the surface through succeeding bond lines. This does not apply to ultrasonic through transmission or reflector plate testing, in which the small-diameter sound beam passes completely through the part. Figure 36 shows the relative defect sensitivity of ultrasonic and bond tester techniques.

Fig. 36 Relative sensitivity of instruments used to inspect bonded laminates of increasing total thicknesses. A, Sondicator, contact method; B, Shurtronics harmonic bond tester; C, Fokker bond tester; D, NDT-210 bond tester; E, Sondicator, through transmission method; F, ultrasonic pulse-echo; G, ultrasonic through transmission

X-Ray Radiography

Radiography is a very effective method of inspection that allows a view into the interior of bonded honeycomb structures. The radiographic technique provides the advantage of a permanent film record. On the other hand, it is relatively expensive, and special precautions must be taken because of the potential radiation hazard. With the radiographic method, inspection must be conducted by trained personnel. This method utilizes a source of x-rays to detect discontinuities or defects through differential densities or x-ray absorption in the material. Variations in density over the part are recorded as various degrees of exposure on the film. Because the method records changes in total density through the thickness, it is not preferred for detecting defects (such as delaminations) that are in a plane normal to the x-ray beam.

Some adhesives (such as AF-55 and FM-400) are x-ray opaque, allowing voids and porosity to be detected in metal-to-metal bond joints (Fig. 5a). This is extremely advantageous, especially for complex-geometry joints, which are difficult to inspect during fabrication. The x-ray inspection should be performed at low kilovoltage (25 to 75 kV) for maximum contrast. A beryllium-window x-ray tube should always be used when radiographing adhesive-bonded structures. To hasten exposures, medium-speed, fine-grain film should be used. Selection of the film cassette should be given special consideration because some cassette materials produce an image on the film at low kilovoltages.

Neutron Radiography

Neutron radiography is very similar to x-ray or γ -ray radiography in that both depend on variations in attenuation to achieve object contrast on the resultant radiograph. However, significant differences exist in the effectiveness of the two methods, especially when certain combinations of elements are examined. The mass absorption coefficients of the different elements for x-rays assume a near-linear increase with atomic number, while the coefficients for thermal neutrons show no such proportionality. The attenuation of x-rays is largely determined by the density of the material being examined. Thus, thicker and/or denser materials appear more opaque. The absorption for thermal neutrons is a function of both the scattering and capture probabilities for each element. The density or thickness of a material or component is less important in determining whether it will be transparent or opaque to the passage of neutrons. For example, x-rays will not pass through lead easily, yet they will readily penetrate hydrocarbons. In contrast, neutrons will penetrate lead and are readily absorbed by the hydrogen atoms in an adhesive or hydrocarbon material.

Neutron Sources. Neutrons are produced from accelerator, radioisotope, or reactor sources. Neutrons, like x-rays, can be produced over an enormous energy range with large differences in attenuation at the various energy levels. The major efforts in neutron radiography have been performed using thermal neutrons because the best detectors exist in this energy regime. Neutron sources generally produce γ -rays of moderate intensity, so that a neutron detector sensitive to γ -ray radiation has a γ -ray image superimposed on the neutron image.

Direct Versus Transfer Method. The most widely used imaging method is conventional x-ray film with converter screens. The rate of radioactive emission of the converter screen divides the photographic imaging into prompt emission or delayed emission. The prompt-emission converters (gadolinium or rhodium) require that the film be present during neutron exposure. This process is referred to as the direct method. The delayed-emission converters (indium or dysprosium) allow for activation of the converter and transfer of the induced image to the film after neutron exposure. This technique is referred to as the transfer method. In the original film, the neutron opaque areas appear lighter than the surrounding material. Image contrast can be increased by making a contact positive print from the film negative. When this is done, the neutron opaque area will be darker than the surrounding material.

Evaluation of Adhesive-Bonded Structures. Hydrogenous (adhesive) materials inspected by neutron radiography can be delineated from other elements in many cases where x-ray radiography is inadequate. However, the neutron radiography inspection method does not appear to be cost effective for the routine inspection of adhesive-bonded structures. It is extremely useful for evaluating the quality of built-in defect reference standards or for failure analysis. If the adhesive is not x-ray opaque, neutron radiography can be used to detect voids and porosity. The hydrogen atoms in the adhesive absorb thermal neutrons, rendering it opaque. Detailed information on this inspection method is available in the article "Neutron Radiography" in this Volume.

Tap Test

Perhaps the simplest inspection method for ensuring that a bond exists between the honeycomb and the facing sheet is that of coin tapping. An unbond is readily apparent by a change in the tone or frequency of sound produced when an adhesive-bonded structure is tapped with a coin or rod as compared to the sound produced for a bonded area. Coins such as silver dollars or half-dollars are used for this test. For standardized production testing, a 13 mm ($\frac{1}{2}$ in.) diam solid

nylon or aluminum rod, 102 mm (4 in.) in length, with the testing end smoothly rounded to a 6.4 mm ($\frac{1}{4}$ in.) radius, is used. Another version of a tap tester is the aluminum hammer shown in Fig. 37.

Fig. 37 Construction details for an inspection tap hammer. (a) Complete assembly. (b) Tap hammer head. Liquid/paste adhesive can be used if desired. The hole in the handle/head can be reduced to provide an interference fit and to preclude the need for the adhesive. Dimensions given in millimeters

Tap testing with a coin or a small aluminum rod or hammer is useful for locating large voids or disbonds of the order of 38 mm diameter or larger in metal-to-metal or thin facing-sheet honeycomb assemblies. Tap testing is limited to the detection of upper facing sheet to adhesive disbonds or voids. It will not detect voids or disbonds at second, third, or deeper adherends. The test method is subjective and may yield wide variations in test results. On thin face sheets, the coin tap will produce undesirable small indentations. In this case, an instrument such as the Shurtronics harmonic bond tester can be used effectively.

Acoustic Emission

In certain cases, acoustic emission techniques are more effective than x-ray or conventional ultrasonic methods in detecting internal metal corrosion and moisture-degraded adhesive in bonded panels. The principle is based on the detection of sound or stress wave signals created by material undergoing some physical or mechanical transformation. Regarding the detection of bond line corrosion, the acoustic signals apparently arise from cavitation or the boiling of moisture within the joint. If the corroded joint is dried out before the acoustic emission test is performed, no acoustic response is obtained.

The equipment consists basically of an amplifier and a piezoelectric sensor with a resonant frequency of about 200 kHz. The emission level is recorded on a chart or counter. Other equipment includes a signal processor, a search unit, a 50-dB preamplifier, an x - y chart recorder or counter, and a hot-air gun (Fig. 38). Simple heating methods employing a hot-air

gun or heat lamp are used to increase emissions from active corrosion sights or to boil moisture. Heating can be done from the search-unit side.

Fig. 38 Acoustic emission detection of active corrosion in adhesive-bonded structures

The panel to be tested is heated to about 65 °C (150 °F) by holding the hot-air gun within 50 to 75 mm (2 to 3 in.) of the surface of the panel for about 15 to 30 s. Immediately after heating, the transducer or search unit is placed a short distance from the heated spot. The transducer is held in position for 15 to 30 s to obtain a complete record of any emission in the heated area. The inspection is conducted on a 152 mm (6 in.) grid. An important consideration during the test is the manner in which the transducer is held against the part surface. Because movement of the transducer can produce appreciable noise, care must be taken in its placement and holding.

Corrosion has been detected in a number of adhesive-bonded honeycomb structures (Ref 7, 8, 9). A direct inspection cost savings of more than 75% over comparative x-ray inspection has been achieved. Additional information on this inspection method is available in the article "Acoustic Emission Inspection" in this Volume.

Special NDT Methods

Holographic Interferometry. Defects such as core-to-skin and core-splice voids, delaminations, crushed core, and bond line corrosion can usually be detected by holographic nondestructive test techniques (Ref 3, 24). A hologram of the test specimen is first recorded by means of laser light reflected from its surface and superimposed on a mutually coherent reference beam in the plane of a high-resolution photographic emulsion. The hologram provides a complete record of all visual information about the entire illuminated surface of the specimen, including the phase and the amplitude of the reflected wave front.

The specimen is then stressed in one of several possible ways, including heat, pressure change, evacuation, and acoustic vibration. A surface displacement differential of only a few microinches between a defective and a good-quality bond is adequate to produce a holographic image. Differential surface displacements, caused by subsurface anomalies, are observed or recorded with one or more of the following three holographic techniques:

- *Real time:* The stress-illuminated specimen is viewed through its developed hologram (made in a different state of stress)
- *Time lapse:* Two holographic exposures are made on the same plate, with the specimen in two states of stress, and then reconstructed
- *Time average:* The hologram is recorded during many cycles of sinusoidal vibration of the specimen

A fluid-gate photographic plate holder provides for the in-place development of holograms and enhances the speed of the operation (Ref 24). Because of the acute sensitivity of holographic interferometry to small disturbances, it is necessary to reduce spurious and unwanted acoustic noise and temperature gradients within the environment of the testing system. Floor vibrations arising from heavy traffic, the loading/unloading of vehicles, and heavy-duty machinery generate noise that must be minimized.

Systems for testing sandwich structures generally use helium-neon gas lasers, which normally deliver between 60 and 80 mW of power at 632.8 nm (6328 Å). This power is sufficient to examine at least 0.19 m² (2 ft²) of surface area, and the deep red color of the light is close enough to the sensitivity peak of the eye for good fringe-to-back-ground contrast.

A typical real-time hologram showing a skin-to-core void revealed by thermal stressing is illustrated in Fig. 39. In large measure, the basic limitation of holography is related to the stressing techniques utilized. Holography cannot be used without a surface manifestation of a defect during stressing. If the material thickness precludes detection of a resolvable fraction of the fringe spacing, then the technique is ineffective. It is not useful for inspecting complex laminates, because of the inability to stress the void areas. Thermal stressing of aluminum is unsatisfactory, because of its high thermal conductivity (heat is transferred laterally rather than vertically through the joint). Holography is satisfactory for inspecting honeycomb structures, but few voids exist at the skin-to-core interface. It is limited in locating voids at honeycomb closures or multilaminate metal-to-metal areas. Numerous flaws in the closure areas of bonded honeycomb assemblies (voids and porosity) detected by ultrasonics and x-ray methods were not detected by holographic interferometry.

Fig. 39 Holographic recording and viewing. (a) Setup for recording hologram. (b) Setup for real-time viewing of hologram. (c) Example of real-time hologram of a flaw (void in adhesive) in a honeycomb core assembly. The part was heated to give thermal stressing.

At Fokker-VFW, a holographic installation for testing bonds was developed and put into use for production inspection (Ref 3). The installation uses a single hologram for components up to 6 m (20 ft) in length. It has adjustable optics for optimum sensitivity and component scanning. The defect area can be magnified and the results presented on a highly sensitive video monitor which can record the information. The bonded components can be deformed by either vibrations or thermal effects.

Interference holography shows much more than just bond defects, and training is needed for personnel to learn to distinguish areas that are defective from those that are merely not ideal (Ref 2, 3, 21). Core-splice location and quality can be inspected, and core machining anomalies are visible. Also, the thermal method is the most practical deformation

method for sandwich structures, especially for graphite-epoxy skins bonded to aluminum core. Extensive studies have shown that thermal deformation is difficult to use for metal-to-metal structures (Ref 21). These difficulties led workers at Fokker to concentrate on vibration testing because of the relation between resonance properties and cohesion quality. Much time will be needed to develop a universal system of quality testing based on interference holography. However, a specific interference holography system has been developed for the inspection of truck and aircraft tires (Ref 25). A wide variety of tire defects have been detected and categorized for both new and retread tires and have been related to durability. Detailed information on this inspection method is available in the article "Optical Holography" in this Volume.

Infrared or Thermal Inspection. The thermal NDT of adhesive-bonded structures has been performed by a variety of techniques, including the following:

- Infrared radiometer testing (Ref 22, 26)
- Thermochromic or thermoluminescent coatings (Ref 22, 27)
- Liquid crystals (cholesteric) (Ref 28, 29)

For infrared radiometer testing, the detector employs a moving heat source and records variations in heat absorption or emission while scanning the part surface. The scanners, or detectors, used in infrared testing are called radiometers. The radiometer generates an electrical signal exactly proportional to the incident radiant flux. Because scanning and temperature sensing are performed without contact, the observed surface is not disturbed or modified in any way. The thermal pattern from the part under test can be observed on a CRT, storage (memory) tube, or x - y recorder.

Tests are performed by heating the sample with a visible-light heat source (quartz lamp or hot-air gun), then observing the surface heating effects with the radiometer. Heat is applied to both bonded and unbonded areas. The bonded areas will conduct more heat than the unbonded areas because of good thermal conduction to the honeycomb structure. The test panel is first coated with flat-black paint to ensure uniform surface emissivity. The sample is then scanned as shown in Fig. 40. Graphs are obtained by connecting the horizontal movement of the sample to one axis of an x - y recorder and the radiometer output to the other axis. Typical line scan and area scan test results are shown in Fig. 40(b) and 40(d), respectively. Similar results are obtained with the AGA Thermovision (in the pitch or catch or through transmission modes) (Ref 22). Good results are generally obtained when testing graphite-fiber or boron-fiber composite face sheets bonded to aluminum core. Honeycomb structures fabricated exclusively from aluminum (skin and core), or aluminum skin bonded to plastic core, are difficult to inspect by infrared methods because of the lateral heat flow in the aluminum face sheets.

Fig. 40 Schematics and readouts illustrating infrared radiometer tests. (a) Arrangement for line scan test. (b) Example of readout and method of void detection. (c) Arrangement for area scan test. (d) Example of readout and method of void detection

Thermochromic or Thermoluminescent Coatings. The use of an ultraviolet-sensitive coating containing a thermoluminescent phosphor that emits light under excitation by ultraviolet radiation (black light) permits the direct visual detection of disbonds as dark regions in an otherwise bright (fluorescent) surface (Ref 22, 27). The coating is sprayed on and dried to a 75 to 130 μm (3 to 5 mil) thick plastic film. Defects appear as darkened areas when the panel is heated to 60 °C (140 °F) and viewed under ultraviolet light (Fig. 41). The defective regions can then be marked on the plastic film with a felt-tip pen. The rate of fluorescent reversal and retention depends on the thermal conductivity of the underlying structure.

Fig. 41 Thermoluminescent coating technique on boron composite aluminum honeycomb flap assembly. (a) Close-up of honeycomb structure. (b) Plot of intensity versus location for bonded joint at locations shown. (c) Plot of intensity versus location for unbonded joint at location shown

Thermochromic paints consist of a mixture of temperature-indicating materials that change color when certain temperatures are reached. Thirty-six materials covering the temperature range of 40 to 1628 °C (104 to 2962 °F) are available, with the low-temperature materials being used for bond inspection. The low-temperature paint changes from light green to vivid blue upon reaching 40 °C (104 °F). The color change will last (in the defect area) for about 15 min based on the relative humidity. The dark areas can be made to revert back to the original color by applying moisture in the

form of steam. The tests can be repeated a number of times without destroying the properties of the paint. The paints are easy to apply and remove.

Liquid crystals are a mixture of cholestric compounds that change color when their temperature changes as little as 0.84 °C (1.5 °F) and they always attain the same color at a given temperature for a specific crystal composition. After suitable surface preparation or cleaning, a thin coating of liquid crystals is applied by spray or brush to the test object surface. When the object is correctly heated (relatively low temperatures) with a heat lamp or hot-air gun, the defects are indicated by differences in color (Ref 28, 29). Unfortunately, the color continues to change through a specific color band as it is heated and cooled. Therefore, the defects must be marked on the surface of the part as they appear and disappear. Photographs can be taken as a record of the test results after specific defects are located. The test can be repeated a number of times without destroying the liquid crystals. In some cases, black paint is required under the liquid crystal coating to obtain uniform emissivity and color contrast in the defect areas. The theory and results obtained using liquid crystals are virtually the same as for thermoluminescent and thermochromic coatings. Detailed information on thermal NDT is available in the article in the article "Thermal Inspection" in this Volume.

Leak Test. A hot-water leak test is generally conducted on all bonded honeycomb assemblies immediately after fabrication or repair. The test is performed by immersing the part in a shallow tank of water heated to about 65 °C (150 °F). The heat causes the entrapped air to expand, and if there are any leakage paths, bubbles will be generated at the leakage site. The panel is monitored visually for escaping bubbles, and the leakage site is marked on the panel for subsequent sealing. A part that leaks after fabrication will generally develop problems in service. After the leak test, the assembly is radiographed for water that may have become entrapped during the leak test. Additional information is available in the article "Leak Testing" in this Volume.

Acoustical holography provides a way to observe the interior properties of composite laminates or adhesive-bonded joints. This acoustical technique employs ultrasound to obtain three-dimensional information on the internal structure of the test specimen. The acoustical hologram is the converter, or recorder, which allows acoustic information to be visualized much as film is the converter or recorder for light. The acoustic imagers employ different holographic recording techniques, depending on the specific application of the instrument (Ref 30).

Liquid-Surface Acoustical Holography. In this method, the liquid surface acts as a dynamic film for momentary storage of the hologram while it is converted to a visual image through the use of coherent laser light. This technique (Fig. 42) allows real-time acoustical imaging, supplying the operator with an instantaneous view of all internal structures. Because the part must be moved through the fixed acoustic beam, part size is a limiting factor in this technique.

Fig. 42 Schematic of a liquid-surface imaging system

Scanning acoustical holography employs a scanning technique to construct the hologram. The hologram is then recorded on either transparency film or a storage oscilloscope. This technique provides a permanent record of the holographic information and allows the operator to observe the reconstructed image at a later time. By illuminating either the liquid-surface hologram or the transparency film with laser light, the operator can immediately observe all interior properties of the test sample. Figure 43 schematically illustrates a scanning holographic system. The capability of acoustical holography to reveal flaws in bonded structure is covered in Ref 31. One drawback to the use of scanning acoustical holography is the high cost of the equipment. In addition, considerable time is needed to reconstruct the various holograms of the entire part.

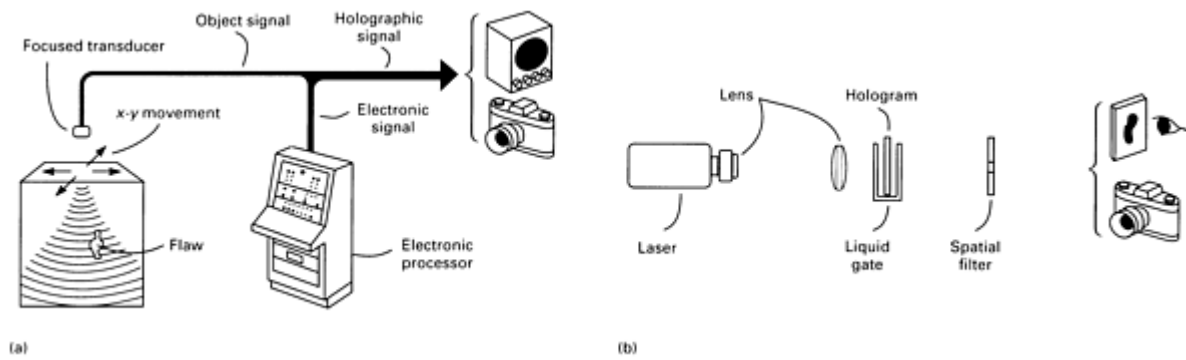

Fig. 43 Schematic of (a) pulse echo acoustical holography system and (b) holographic reconstruction unit

Selection of NDT Method

A universally accepted single test method for evaluating bonded structures has not yet been developed. Therefore, a combination of test methods is required for complete and reliable inspection. Generally, selection of the test method is based on:

- Part configuration and materials of construction
- Types and sizes of flaws to be detected
- Accessibility to the inspection area
- Availability of equipment/personnel

The application of NDT methods in the production cycle for honeycomb sandwich panels generally includes the following:

- Material property tests
- Surface preparation checks (wedge crack, T-peel, and so on)
- Verifilm (prebond) tooling check
- Visual inspection
- Hot-water leak check
- Radiographic check for water and other internal discontinuities
- Ultrasonic C-scan for high-resolution inspection of skin-to-core bond
- Manual inspection of doublers, close-out members, and so on, using acoustic methods such as pulse-echo ultrasonic, Shurtronic harmonic bond tester, or Fokker bond tester

Built-in defects were produced in typical laminate and honeycomb specimens. These specimens were evaluated by state-of-the-art NDT methods to determine which methods reliably detected the different defects. The results of this investigation are given in Table 3 for adhesive-bonded laminates and in Table 4 for adhesive-bonded honeycomb structures (Ref 6). The NDT methods described in this section are used to test sandwich structures having aluminum or titanium skins and aluminum core. Most of the methods can be effectively applied to structures with metal facing sheets and nonmetallic core and structures with graphite fiber, boron fiber, and fiberglass face sheets bonded to aluminum core. Only a limited number of the methods are applicable for structures having both core and facing sheets made from nonmetallic materials.

Table 3 Correlation of NDT results for built-in defects in laminate panels

Laminate defects	NDE method ^(a)												Remarks
	Radiography		Ultrasonic bond testers				Ultrasonic inspection ^(f)					Coin tap test	
	Low-kilovolt x-ray	Neutron radiography	Fokker bond tester	Sondicator	Harmonic bond tester	210 sonic bond tester	Contact pulse echo	Contact through transmission	Immersion C-scan pulse echo	Immersion C-scan through transmission	Immersion C-scan through reflector plate		
1. Void	^(b)	D	D	D	D	D	D	D	D ^(c)	D	D	PD ^(e)	^(b) , ^(c) , ^(e) , ^(g)
2. Void (C-14 repair)	^(b)	D	D	D	D	D	D	D	D ^(c)	D	D	PD ^(e)	^(c) , ^(e)
3. Void (9309 repair)	^(b)	D	D	D	D	D	D	D	D ^(c)	D	D	PD ^(e)	^(c) , ^(e)

Nondestructive Inspection of Adhesive-Bonded Joints*

Donald J. Hagemaiier, Douglas Aircraft Company, McDonnell Douglas Corporation

NDT in the Product Cycle

Nondestructive testing serves as a basis for process control and serves to establish quality control standards. The acceptance or rejection of a bonded assembly is directly related to the quality level desired by the designer. The quality level, in turn, is based on the importance of the part or component in terms of performance and safety. The frequency/severity flaw criteria and sensitivity of the test should be based on the desired quality level. To avoid unwarranted inspection costs, it is advisable to divide the bonded joint into zones based on stress levels or criticality of part function. Bonded joints are generally designed to withstand shear loads. Stress analysis of bonded joints reveals that the outer edges of a bonded joint will be subjected to higher stress levels than the center of the joint. Therefore, higher quality may be desired at the edges, and parts should be zoned accordingly. The zoned area should be dimensioned so that the inspector can define the two different zones prior to inspection. Figure 44 shows an example of quality zoning for bonded laminate skin splice. A definition of inspection grade numbers versus allowable void sizes is illustrated in Fig. 45.

Fig. 44 Schematic of bonded joint divided into quality zones based on design shear stresses. The example shown is a longitudinal skin splice with an internal longeron. Quality grade 1 is within 13 mm ($\frac{1}{2}$ in.) of the edge of any bonded member, and grade 2 is the bond between any two grade 1 bonds.

Fig. 45 Definition of acceptance grades for voids or unbonds

For multiple bond line joints, it may not be possible to inspect to a high quality at the edge of all adherends, because of the loss of test sensitivity at each successive bond line below the surface. If the edges of a bond joint are stepped or staggered, high-quality inspection is possible at the edges of all bond lines. The width of the step should be large enough to accommodate the test instrument probe. Joint edges that are not stepped should be inspected from opposite sides.

Acceptance/Rejection Criteria

Before inspection can be performed on a bonded structure, accept/reject criteria must be established by engineering. These criteria are usually in the form of frequency (number of flaws per unit area) and/or severity (maximum allowable size flaw data). To avoid unnecessary rejections, engineering must not specify unrealistic or overly conservative criteria. The frequency and severity criteria should be based on sound engineering judgement as related to calculated levels. It should be noted that flaws do not grow under cycle loads if good, durable adhesives are used and if generous overlaps exist.

Military Guidelines. For military contracts, the guidelines or requirements for preparing such criteria are specified in MIL-A-83377 (Ref 32). Specific acceptance criteria for adhesive-bonded aluminum honeycomb structures are specified in MIL-A-83376 (Ref 33). Specification MIL-A-83377 states that the contractor shall prescribe nondestructive tests and a complete NDT process specification when required by MIL-I-6780 in evaluating the quality of adhesive-bonded

structures (Ref 34). The NDT process specification must be submitted for approval by the government prior to bonded assembly production. The contractor is required to specify the type and size of the defects that are acceptable. The size of the defect must be consistent with the capability of the NDT method to be used, realizing that NDT methods and instrumentation may have different capabilities. Application of the various NDT methods is limited by material types and design configuration. For aluminum honeycomb sandwich, the allowables of MIL-A-83376 can be used, if determined by the contractor to be acceptable minimums for the particular application.

Specification MIL-A-83377 also requires that the NDT of adhesive-bonded structures be performed only by qualified NDT personnel. Personnel qualification requirements for NDT are specified in MIL-STD-410 (Ref 35).

Records and Specifications

It is recommended that four basic types of inspection records be prepared and maintained. They are specifications, inspection log, detailed written test procedure, and rejection or nonconformance record.

Specifications. Test method specifications should be obtained for each production inspection instrument to be used--for example, Fokker bond tester (Ref 4), 210 bond tester, harmonic bond tester, Sondicator, and so on). Each specification should specify controls for the particular method and should define reference standard configurations. In addition, an acceptance criteria specification should be prepared.

Inspection Log. The production inspection personnel should maintain a daily inspection log. This log should contain the part number, part dash number, part serial number, fabrication outline serial number, inspector name or stamp, date and method of inspection, and a remarks column to indicate pass or reject. The rejection tag number can be entered, along with a description of the flaw, noting its exact location.

Detailed Written Test Procedure. Nondestructive testing inspections should follow a detailed written procedure for each component tested. The written procedure must comply with the test method specification requirements and, as a minimum, must include:

- A sketch of the part or configuration showing in detail the part thickness, alloy material and temper, and the adhesive system used
- Manufacturer and model number of instrumentation to be used
- Model or designation number of probe to be used
- Any recording, alarm, or monitoring equipment and test fixtures or inspection aids that are to be used
- Applicable reference standard(s) serial number and design description
- Type of fluid couplant to be used
- Instrument calibration procedure, if required
- Testing plan. The part surface from which the test will be performed, the testing technique(s) for each joint, and the maximum probe index or shift per scan should be described
- Acceptance limits for each joint of the assembly
- Reference point or identifying mark, which is placed on each part prior to inspection; this mark is used for orientation when reviewing inspection results
- Outline of the areas where multiple layers of adhesive have been used
- Identification of section area changes not visible to the inspector
- Verification of the test procedure on a production part prior to approval

Rejection or Nonconformance Record. All nonconforming flaws should be described on a rejection tag. The inspection agency should outline on the part surface the location and shape of unacceptable bond line flaws. If it is necessary to mark the part permanently, the inspector must remove the couplant and wipe with solvent the area to be marked, and then reapply the marks. Next, the marks are covered with a very light coat of clear epoxy enamel. Marking the problem areas in this way facilitates their location after the part has been in service.

Reference Standards

Reference test standards for calibrating and standardizing the bond inspection instruments are essential. Even with adequate reference standards, inspection often produces conflicting information or a deviation of results. In these cases, more than one inspection method should be used in order to improve the accuracy of the data and to define the deviating condition. Under ideal conditions, the test standard with built-in defects of selected sizes should closely duplicate the structure adherends to be inspected. The laminate skin should be of the same thickness, and the honeycomb core should be of the same size and density. Other variations to be encountered in the test specimen, such as tapered core, chemically milled skins and doublers, and so on, should be incorporated into the test standard.

Except for built-in defects, the test standard for adhesive-bonded structures should be fabricated in the same manner as the production assembly. The void or defect should be introduced in the same bond line as that to be inspected in the structure. The standard can be a series of simple test specimens composed of details identical to the several areas of the assembly to be inspected and having a bond of good quality but with controlled or known defect locations and size.

Attempts to produce voids or controlled understrength bonds by the local application of grease or other foreign materials have been found to be ineffective. All adhesives and primers vary and may not respond to the following suggested methods of standard preparation. Therefore, the finished standards should be evaluated by various NDT methods prior to validation of their use as an inspection standard. Neutron radiography is an excellent method for verification if voids, porosity, or both have been generated in the standard. The standard must then be inspected by the test instrument chosen for the particular part to confirm its ability to locate the flaw.

Metal-To-Metal Reference Standards. Various methods have been developed for producing simulated voids, porosity, or unbonds in metal-to-metal bonded laminates. Numerous ways to produce reference standards for metal-to-metal bonded joints or assemblies are described in Ref 10. Because of the variety of such standards, it is not possible to describe all of them in this article, and it is recommended that the reader consult the references for additional information.

Figure 46 shows two methods for producing standards for simulated skin-to-adhesive unbonds. The method 1 or 2 standards are useful for all NDT application methods provided the Teflon or Mylar inserts do not bond to the adherends.

Fig. 46 Two methods of fabricating unbond reference standards. (a) Method 1 uses two pieces of aluminum sheet that have been anodized and primed and then bonded together with a piece of adhesive that has various-size cutouts filled with 0.13 mm (0.005 in.) thick Teflon disks. (b) Method 2 uses metal as in method 1, but the voids are produced by placing a disk sandwich of Mylar and scrim cloth of desired size on the uncured adhesive. The assembly is then bonded.

Void, Porosity, and Unbond Standards. Voids or unbonds of specified sizes are difficult to produce because free-flowing adhesive may fill the anticipated void or unbond area. One researcher was successful in producing natural flaws in the adhesive layer of metal-to-metal bond joints (Ref 1). By trial-and-error methods, defect conditions such as a void produced by removing a section of adhesive, a void produced by inserting a 0.64 mm (0.025 in.) diam wire between adherends, and porosity caused by inserting a 0.38 mm (0.015 in.) diam wire between adherends prior to bonding can be produced at specific locations in a bonded joint and with the desired sizes to be detected in an x-ray radiograph.

The methods 3, 4, and 5 standards (Fig. 47) are useful for manual bond test methods (such as Fokker, Harmonic, and 210 bond test applications) and for pulse-echo ultrasonics. The holes at the edge and center of the method 3 standard are required if pinch-off of adhesive occurs near the edge with thicker adhesive near the center of the standard. For maximum sensitivity, a bond joint should be inspected from both sides, and method 3 and 4 standards are used. If the joint can be inspected from only one side, the method 5 standard is used. Holes are drilled after the part is bonded.

Fig. 47 Additional methods for fabricating unbond reference standards. (a) Method 3 uses three flat, unchamfered aluminum sheets of different thicknesses. This standard can be inspected from either side. Hole diameters can vary from 6.4 to 13 mm ($\frac{1}{4}$ to $\frac{1}{2}$ in.) and are free of adhesive. (b) Method 4 uses two chamfered aluminum sheets of different thicknesses with drilled holes 9.5 or 13 mm ($\frac{3}{8}$ or $\frac{1}{2}$ in.) in diameter (free of adhesive) and edge voids made by inserting Teflon shims of the size shown. Shims must be removed after bonding. This standard can be inspected from either side. (c) Method 5 is a flat step standard using a buildup of various sheet thicknesses that matches the structure to be inspected. There should be no adhesive at the base of the holes. This standard should be inspected from the top side only. Dimensions given in inches

Standards containing porosity can be made by the wire insertion method or by bonding a large-area panel 0.6×0.6 m (2×2 ft, minimum) at low pressure (275 kPa, or 40 psi, maximum). In bonding with a mat (nonwoven) carrier, the adhesive pinches off at the outer edge, producing a picture frame of gross porosity close to the edge. Scattered porosity and some small voids are produced throughout the rest of the panel. After ultrasonic C-scan or radiographic inspection, representative specimens or small standards can be removed from the panel. The methods for producing voids and porosity are useful for creating defects at specific locations in slow-cycle fatigue test specimens. This type of specimen is used to study the effects of defects under load, cycle rate, or environment.

Burned-Adhesive Standards. Method 6 (Fig. 48) is used to fabricate a standard representing burned adhesive caused by improper drilling or sawing of bonded panels. If improper drills, excessive drill speed and feed, or no coolant is used, burning of the adhesive adjacent to the hole may occur.

Fig. 48 Additional methods for fabrication unbond reference standards. (a) Method 6 presents a burned-adhesive standard in which (1) is a good-quality hole, (2) is a slightly burned adhesive, (3) is a grossly burned adhesive, and (4) is a grossly burned edge caused by abusive band sawing. (b) Method 7 becomes a variable-quality standard by inserting tapered shims between face and back sheet before bonding. Three 13 mm ($\frac{1}{2}$ in.) wide shims are shown in place. Tapered shims cause increasing porosity going from right to left. Half of the face sheet can be removed after inspection to reveal the condition of the adhesive. Dimensions given in inches

Variable-Quality Standards. Method 7 (Fig. 48) is a way to fabricate a variable-quality standard. Through the use of tapered shims, good quality is obtained at the thin end and poor quality at the thick end. Figure 49 shows a positive reproduction made from an x-ray negative of AF-55 adhesive in a tapered standard. For visual correlation, only the right-hand upper skin need be removed from the panel, thus revealing the variable adhesive quality. The left-hand side is kept intact to determine variations in NDT instrument response to different adhesive quality conditions.

Fig. 49 Positive print from x-ray negative of tapered-shim variable-quality standard shown as method 7 in Fig. 48

Calibration of Bond Testers. When the size of the unbond or void is not of primary concern or to calibrate instruments to a bond/no-bond response, the following standards prove adequate. These standards are especially useful for resonant-type instruments such as the Fokker, Harmonic, Sondicator, and 210 bond testers. They relate well to the bonded part when a 120 to 175 °C (250 to 350 °F) curing epoxy or epoxy phenolic resin system, which does not attenuate the ultrasonic energy, is used. Basically, the standards are made by cutting 38 mm (1.5 in.) diam holes in a 13 mm ($\frac{1}{2}$ in.) thick plywood panel and then bonding 75 × 75 mm (3 × 3 in.) aluminum sheets, using room-temperature curing adhesives, so that the center of the sheet is centered over the holes in the plywood. The thickness of the aluminum sheets is chosen to match the thickness of the aluminum adherends of the test part. The number of sheets is governed by the number of adherends in the test part. When the aluminum sheet is bonded to a wooden base, it does not resonate freely and reacts similarly to unbonds in the part being inspected.

Honeycomb Reference Standards. Method 1 or 2 (Fig. 46) is used to create a void or unbond reference standard for honeycomb. For honeycomb standards, the unbonds are created between the adhesive-to-skin and adhesive-to-core interfaces. Skin-to-adhesive voids or unbonds are usually easier to detect than adhesive-to-core unbonds. Another way to prepare a void or unbond standard for a honeycomb panel is illustrated in Fig. 50. This standard is useful when attempting to detect unbonds on both sides of the panel if inspection can be performed from only one side.

Fig. 50 Construction details for making a honeycomb standard for voids and unbonds. (a) Back skin and core cut out to desired diameter. Cutting through face sheet adhesive shows skin-to-adhesive unbond; cutting to the adhesive shows adhesive-to-core unbond. (b) Cutting through back skin first to the adhesive to show skin-to-adhesive unbond and then through the adhesive to show adhesive-to-core unbond. Note that Teflon disks can be used to help separate adhesive from skins at cutouts. All tests are to be made from the face skin side.

Honeycomb crushed core standards are made by inserting 25 mm (1 in.) diam, 0.13 and 0.25 mm (0.005 and 0.010 in.) thick metal disks between the skin and core and then applying pressure. The disks are removed and the panel is bonded. The 0.13 mm (0.005 in.) crushing is very subtle and is difficult to detect radiographically. The 0.25 mm (0.010 in.) crushing is easily detectable.

Water intrusion standards are produced by hot-bonding one skin to the core, adding various quantities of water into the cells, and then cold-bonding the second facing sheet in place.

Core-splice standards are made by cutting the edges of the core with a taper and then applying foaming adhesive to one side of the splice before bonding. Voids in the foaming adhesive are detectable by low-kilovoltage radiography. Core-to-closure voids are made by eliminating foaming adhesive at small areas along the joint.

Separator sheet standards are produced by bonding-in a desired size of the material at the skin-to-adhesive and adhesive-to core interfaces.

A blown core standard can be made by mechanically damaging the core prior to bonding.

Corroded core or core-to-adhesive corrosion standards can be made by bonding only one skin to the core (open-face honeycomb) and then alternately spraying the honeycomb side in a salt spray system. The degree of corrosion can be monitored visually. If it is desired to close up the panel, the second facing sheet can be cold-bonded to the other side of the core.

Substitute Standards. When the ideal standards are not available, other standards of construction similar to that of the test part can be used. However, honeycomb standards should not be used for metal-to-metal laminate structure, and vice versa.

Inspection Without Standards. When standards are not available, a known undamaged area can be used as the standard. Repaired areas are inspected by comparing them to an unrepaired area. The instrument reading may change because of structural changes resulting from the repair. Repeated inspection scans must be conducted under various instrument settings, and the inspection should be verified by other methods and/or instruments. A knowledge of the part configuration (for example, number of bond lines, adhesive thickness, skin thickness, and so on) is essential for interpreting the test results.

Nondestructive Inspection of Adhesive-Bonded Joints*

Donald J. Hagemaiier, Douglas Aircraft Company, McDonnell Douglas Corporation

Evaluation and Correlation of Inspection Results

The experience, confidence, and effectiveness of NDI technicians and engineering personnel are gained by correlating NDI results with destructive testing. Comparisons can be made between the NDI results and the actual size, shape, location, and type of defect. Mistakes will occur in the early stages of the bonding program, but if accurate records, photographs, and sketches are kept, they can serve as effective training devices. Sections of defective parts should be kept for training purposes. All these items add to the confidence of the inspector in evaluating and accurately reporting defects. They also add to the engineer's confidence in the inspector and in the data reported by the inspector.

Procedure

Before new adhesive-bonded assemblies are fabricated on a mass production basis, the first assembly is evaluated by numerous methods. Inspections are performed and NDT results are evaluated to detect any variations in the part that are indicative of discontinuities. The part is then cut up, and special precautions are taken to section through the discontinuities or to separate the joint at the discontinuity to identify and verify the NDI results. To determine which NDT method(s) detected the discontinuity, the NDI technicians use different color markings--for example, blue for x-ray, green for ultrasonic, red for a bond tester, and so on. These markings can be affixed to the surface of the part or placed on a transparent overlay of the part. When the part is sectioned, the results will identify which NDT method(s) correctly identified the location, size, shape, and type of discontinuity. Although it is expensive, cutting the adhesive-bonded assemblies is sometimes the only way to determine the nature of the discontinuity or to verify its existence. All inspection results should be carefully documented for future reference.

Once a highly confident inspection technique is established, the remaining defective assemblies can be used for developing repair procedures. The original NDI techniques can then be used for determining if the repairs are effective. In some cases, defective parts are consistently produced, and the material, production process, or design must be changed to correct the condition. This condition is usually evident when the same type of defect occurs in the same location in all manufactured parts.

Reliable feedback from manufacturing personnel is beneficial to the NDI technician. This information can include such items as too high or too low an oven temperature, incorrect heat-up rate, leaks in the vacuum bag, additional layers of adhesive added at a particular spot in the assembly, and so on. With this information, the NDI technician is better prepared to inspect a particular group of parts.

Destructive Correlations of NDI Results

Following is a typical example of correlating NDI results by destructive testing. In this example, a metal-to-metal joint containing a bonded doubler and longerons and frames was rejected for numerous voids and porosity. The initial inspection was performed using the Fokker bond tester, and the defective areas were marked on the surface of the part, as shown in Fig. 51(a). The inspection results were verified using the 210 bond tester. The part was then sent out for thermal neutron radiography. There was excellent correlation between the Fokker bond test results and the neutrograph (Fig. 51b).

Fig. 51 Correlation of NDI results. The same specimen was inspected by (a) Fokker bond tester and (b) neutron radiography. See text for discussion.

The panel was then ultrasonically C-scanned using the through transmission technique. Again, the correlation was excellent, as shown in Fig. 52. A plastic overlay was made to record the Fokker bond tester results.

Fig. 52 Ultrasonic C-scan recording of panel in Fig. 51 showing voids and porosity. Through transmission method was used with low-gain (31 dB).

The part was then subjected to chemical milling to dissolve the aluminum adherends, leaving the adhesive layer intact. The adhesive thickness was measured and recorded. The destructive to nondestructive correlation was again excellent and revealed that the adhesive thickness in and around the defects was greater (0.33 to 0.46 mm, or 0.013 to 0.018 in.) than in the nondefective areas (0.18 to 0.28 mm, or 0.007 to 0.011 in.). In addition to the correlations noted above, lap shear specimens could have been made through the different defect conditions, and variations in bond strength could have been determined.

Because of the variety of defects that can occur in honeycomb assemblies, defects detected by one test method should be verified by an additional, but similar test method. Time and facilities permitting, the assembly should also be x-rayed in the defective area.

Ultrasonic Wave Interference Effects

In the ultrasonic inspection of adhesive-bonded joints, the following two conditions may cause ultrasonic wave interference (Fig. 24) effects:

- When inspecting bond lines under tapered metal doublers
- When inspecting close to the edge of a bonded laminate and the adhesive is thin due to pinch-off (Ref 10)

Ultrasonic theory predicts that constructive interference (increased amplitude) occurs when the transmitted and reflective waves are in phase with one another (Ref 36, 37). Conversely, destructive interference (decreased amplitude) occurs when the transmitted and reflected waves are 180° out of phase with one another. Destructive wave interference causes a drop in signal amplitude, and the C-scan recorder will not record in the area of interference. An inexperienced operator might misinterpret these areas as voids or unbonds. However, interference effects (caused by tapered adherends) are uniform across the part, resulting in bands of light and dark on the C-scan recording (Ref 10). When destructive interference effects are shown in C-scan recordings of bonded splices having tapered adherends, the bond joints are given another inspection by a different method, such as the Fokker bond tester.

Destructive wave interference effects can also be seen in C-scan recordings of adhesive-bonded laminates made with an adhesive having a mate carrier. It is less evident in laminates bonded with adhesive having a woven carrier. The destructive interference effects are most evident near the outer edges of the assembly where the adhesive is pinched off to thicknesses of 0.08 mm (0.003 in.) or less. The interference effects are frequently dependent and therefore will change position if the test frequency is altered (Ref 36, 37). Less wave interference is experienced with through transmission testing than with pulse-echo testing at similar frequencies. Bonded laminates exhibiting destructive wave interference effects require inspection by another test method in the area in question to verify bond quality.

Correlation of Bond Strength and Fokker Bond Tester Readings

The ability of the Fokker bond tester to measure bond strength is completely dependent on the accuracy of the correlation curves, which plot Fokker readings versus either lap shear strength (for metal-to-metal joints) or flatwise tensile strength (for honeycomb joints). For metal-to-metal joints, the correlation is made between the Fokker A-scale readings and tensile lap shear strength. For honeycomb structure, the correlation is made between Fokker B-scale readings and flatwise tensile strength.

Flatwise tensile specimens are prepared in accordance with MIL-STD-401 (Ref 38), except that the adherends and core should simulate those of the bonded test assembly being tested. Fabrication procedures should be identical to those used in preparing the assembly to be tested. Specimens are prepared with various degrees of bond quality by the introduction of porosity in the cured adhesive. The degree of porosity increases with the thickness of the adhesive layer. Figure 53 illustrates the procedure for honeycomb-to-skin joints.

Fig. 53 Schematic of honeycomb sandwich test panel

Nondestructive testing of the panels is performed in accordance with procedures outlined in MIL-STD-860 (Ref 23) or as specified in the Fokker bond tester training manual. Instrument readings should be taken within predetermined areas of the test specimen. Each reading should be recorded and correlated with the probe location on the specimen. The

specimens are then destructively tested, and the tensile strength values are recorded. Flatwise tensile strength should be plotted versus average ultrasonic readings for each specimen and a representative curve drawn through the plotted points. Two correlation curves should be drawn for specimens with dissimilar thickness adherends. A typical correlation curve for Fokker B-scale readings versus flatwise tensile strength is shown in Fig. 54.

Fig. 54 Typical Fokker B-scale correlation curve versus honeycomb flatwise tensile strength. Cell structure: 0.64 mm (0.025 in.) face skin, 3.18 mm (0.125 in.) cell size, and 0.025 mm (0.001 in.) foil thickness. Probe used was No. 3414.

Effect of Porosity and Voids on Bond Testing. A relationship can be established between Fokker bond tester A-scale frequency shift and lap shear strength as related to porosity. Tests have shown that the percentage of porosity increases with adhesive thickness (single layer) (Ref 5, 10). Porosity first appears at an adhesive thickness of 0.25 mm (0.010 in.) and becomes almost completely void at 0.51 mm (0.020 in.) in thickness.

The first step is to produce high-quality lap joints (25.4 mm, or 1.0 in., wide by 13 mm, or $\frac{1}{2}$ in., overlap) containing 100, 80, and 50% width bond lines, as shown in Fig. 55. The test specimens are approximately 178 to 203 mm (7 to 8 in.) long, and a minimum of six specimens should be made for each percentage bond and thickness, that is, 1.0 mm/1.0 mm (0.040 in./0.040 in.) (in general, the t_1 thickness is equal to the t_2 thickness) and so on. Typical average lap shear values for 2024-T3 and FM-73 adhesive are shown in Fig. 56.

Fig. 55 Lap shear test coupon. Dimensions given in millimeters

Fig. 56 Variation in lap shear strength with t/l ratio and bond length using aluminum alloy 2024-T3 and adhesive FM-73. t_1/t_2 (mm): 1.0/1.0, 1.3/1.3, 1.6/1.6, and 1.8/1.8.

The second step is to make specimens with increasing thickness of the single adhesive layer. This will produce specimens of variable quality resulting from porosity. To obtain the quality variation, spacer shims are used, as shown in Fig. 57. The thickness of the spacers is increased in steps (0.10 mm, or 0.004 in., per step) from 0.10 to 0.51 mm (0.004 in. to 0.020 in.), resulting in a highly porous bond joint. The lap shear specimens are numbered and neutron radiographed. The specimens are then Fokker bond tested, and the A-scale readings are recorded for each specimen. The lap shear coupons are cut from each panel, and the adhesive thickness (for each specimen) is accurately measured. The adhesive will generally be found to be slightly thicker than the associated shim. The lap shear test is performed in accordance with Federal Test Method Standard No. 175, method 1033, or Federal Specification MMM-A-132. The neutron radiographs indicate areas of nonuniformity of porosity, and results from these nonuniform areas should be discarded.

Fig. 57 Metal-to-metal lap shear test panel.

The third step is to prepare shimmed specimens using additional layers of adhesive. This will produce good-quality specimens of thick adhesive. The panels are neutron radiographed, Fokker bond tested, cut into specimens, and lap shear tested, with the data subsequently evaluated. Plots of lap shear strength versus adhesive thickness for the single porous layer and multiple nonporous layers of FM-73 are shown in Fig. 58.

Fig. 58 Lap shear strength versus adhesive thickness for porous and nonporous adhesives. Adherends, 1.6 mm/1.6 mm; adhesive, FM-73 with mat carrier; primer, BR127

The fourth step is to plot lap shear strength versus Fokker A-scale readings for each adherend thickness (Fig. 59). If the thickness of the adherends is not equal, the back (unprobed) thickness is plotted. Unequal-thickness adherend specimens are tested from both sides and two quality curves are established. With reference to Fig. 59 and 60, the bond strength can be determined for 100, 80, and 50% specimens having various thickness or t/ℓ ratios. By evaluating all the data, the following classes for single-layer (porous) and multiple-layer (nonporous) joints can be specified:

- *Class A*: Greater than 80%
- *Class A/B*: Greater than 65%
- *Class B*: Greater than 50%
- *Class C*: Greater than 25%

Fig. 59 Lap shear strength versus Fokker bond tester quality units. Bond tester, model 70; probe, 3814; adherends, 1.6 mm/1.6 mm; adhesive, FM-73; primer, BR127

Fig. 60 Establishment of acceptance limits (sheet to sheet)

A-Scale Frequency Shift Versus Bond Quality. The large scatter in results for the 25% quality level specimens can be attributed to the extensive porosity in these specimens. This does not pose a problem to the inspector, because quality levels below 50% are usually not acceptable. The actual relationship between the A-scale frequency shift (as seen by the inspector) and the bond quality (class) is illustrated in Fig. 60.

Cohesive Bond Strength Acceptance Limits. Finally, the acceptance limits are incorporated into a table for use by the inspector. Table 5 lists the acceptance limits for single bond line joints with FM-73 adhesive and specific thickness adherends. Establishing Fokker quality diagrams for multiple bond line joints is possible but complicated. Fokker-VFW should be contacted to obtain the recommended procedures for developing such quality diagrams.

Table 5 Fokker cohesive bond strength acceptance limits for single bond line using FM-73 adhesive

Lower sheet thickness		Model 70 probe	Upper limit ^(b)	Lower limits ^(a)			
mm	in.			Class A ^(c) 80%	Class A/B ^(c) 65%	Class B ^(c) 50%	Class C ^(c) 25%
1.0	0.040	3814	>R8	>L54	>L40	>L25	> L10
1.3	0.050	3814	>R10	>L48	>L36	>L20	> L9
1.6	0.063	3814	>R12	>L42	>L30	>L18	> L8
1.8	0.071	3814	>R16	>L40	>L28	>L18	> L7
2.1	0.081	3814	>R18	>L38	>L25	>L15	>L6

(a) Skin/stringer and skin/frame bonds shall be Class minimum; doubler/skin bonds shall be Class A/B minimum. Additional adhesive layers shall not yield readings less than the lower limits by the following factors: 2 layers (-15); 3 layers (-25); 4 layers (-30).

(b) R, right-hand side.

(c) L, left-hand side

Nondestructive Inspection of Boilers and Pressure Vessels

Introduction

DURING THE FABRICATION of a boiler, pressure vessel, and such related components as boiling water reactor piping or steam generator tubes, various types of nondestructive inspection (NDI) are performed at several stages of processing, mainly for the purpose of controlling the quality of fabrication. In-service inspection is used to detect the growth of existing flaws or the formation of new flaws. This can be done while the vessel is in operation or down for servicing. The inspection methods used include visual, radiographic, ultrasonic, liquid penetrant, magnetic particle, eddy current, and acoustic emission inspection, as well as replication microscopy and leak testing. The assurance of component quality depends largely on the adequacy of NDI equipment and procedures and on the qualification of personnel conducting the inspection. In many cases, nondestructive inspection, both prior to and during fabrication, must be done to sensitivities more stringent than those required by specifications. The use of timely inspection and rigid construction standards results in the reduction of both the costs and delays due to rework.

Quality planning starts during the design stage. For inspections to be meaningful, consideration must be given to the condition of the material, the location and shape of welded joints, and the stages of production at which the inspection is to be conducted. During fabrication, quality plans must be integrated with the manufacturing sequence to ensure that the

inspections are performed at the proper time and to the requirements of the applicable standard. In the newest nuclear plants, quality design planning includes:

- Avoidance of complex weld geometries to facilitate attachment of ultrasonic transducers to the surface at the best positions
- The increased use of ring forgings for pressure vessel components; this means that there are no longitudinal welds that have to be inspected in service. The result is a reduction in the amount of in-service inspection and man-rem exposures
- Incorporating large numbers of access points for introducing mechanized inspection equipment, which can be operated remotely, thus avoiding exposures to operators and enabling more accurate processing than is possible with handheld inspection equipment
- The elimination of welds between cast austenitic components; inspection of welds through cast welds is difficult because they are opaque to ultrasonic inspection to a large degree (Ref 1)

Nondestructive Inspection of Boilers and Pressure Vessels

Boiler and Pressure Vessel Code and Inspection Methods^{*}

Pressure vessels--both fossil fuel and nuclear--are manufactured in accordance with the rules of the applicable American Society of Mechanical Engineers (ASME) Boiler and Pressure Vessel Code (Ref 2). For nuclear vessels, section XI of the ASME code establishes rules for continued nondestructive inspections at periodic intervals during the life of the vessel. One feature of the rules in section XI is the mandatory requirement that the vessel be designed so as to allow for adequate inspection of material and welds in difficult-to-reach areas. Section III of the code describes the material permitted and gives rules for design of the vessel, allowable stresses, fabrication procedure, inspection procedure, and acceptance standards for the inspections.

Pressure vessels are constructed in various sizes and shapes, and some of the largest are those manufactured for the nuclear power industry. Some pressure vessels are more than 6 m (20 ft) in diameter and 20 m (70 ft) in length and weigh almost 900 Mg (1000 tons). Thickness of the steel in the walls of these vessels ranges from about 150 mm (6 in.) to more than 400 mm (15 in.), although many pressure vessels and components are fabricated from much thinner material. Joining of the many vessel sections is accomplished by welding. Welders of pressure vessels are qualified according to section IX of the ASME Boiler and Pressure Vessel Code, and welding is done in accordance with qualified welding procedures. Nondestructive inspection of welds is only a part of the inspection requirements; the materials themselves must be inspected prior to welding. For pressure vessels that are not constructed according to the ASME code, it is a matter of agreement between the manufacturer and the user as to whether NDI methods are to be employed and which method or methods are to be used.

Nondestructive Inspection Methods. An appendix to each section of the ASME code establishes the methods for performing nondestructive inspection to detect surface and internal discontinuities in materials. Four inspection methods are acceptable: radiographic, magnetic particle, liquid penetrant, and ultrasonic inspection. All these methods are mandatory for nuclear vessels, for section III, and for division 2 of section VIII of the code. Ultrasonic inspection is listed in division 1 of section VIII of the code as nonmandatory. Leak testing, eddy current inspection, acoustic emission inspection, and visual inspection are included in section V. Details as to which method is to be used and the required acceptance standards are specified in the appropriate articles on materials and fabrication. All NDI personnel must be qualified and certified to SNT-TC-1A procedures (Ref 3).

Radiographic Inspection. Methods of radiographic inspection are extensively detailed in the ASME codes; radiography using either x-rays or radioisotopes as the radiation source is permitted. Radiography is the oldest inspection method detailed in the codes and is probably the most understood and the most widely accepted. A principal reason for its

wide use is that radiography provides a permanent record of the results of the inspection. This record is important because the inspector can review the radiographs at any time to ensure that federal, state, or insurance requirements have been met.

Acceptance standards were developed according to the limits of radiography (what can or cannot be detected by the method) and by the quality level obtainable by the manufacturing practices used to produce the vessels. Essentially, the acceptance standards do not permit the existence of indications of the following types of flaws: cracks, incomplete fusion, incomplete penetration, slag inclusions exceeding a given size that is not related to the thickness of the part, and porosity that exceeds that presented in illustrated charts provided in the codes. These standards result from the ability to distinguish among porosity, slag, and incomplete fusion in the radiograph; more important, they also mean that no indications of cracks or of incomplete fusion are permitted.

Magnetic Particle Inspection. The procedures for magnetic particle inspection reference ASTM E 709 (Ref 4) or section V of the ASME code for the method. Acceptance standards permit no cracks, but rounded indications of discontinuities are permitted provided they do not exceed a certain size or number in a specified area. Magnetic particle inspection is universally used on ferromagnetic parts, on weld preparation edges of ferromagnetic materials, and on the final welds after the vessel has been subjected to the hydrostatic test. A magnetic particle inspection must be conducted twice on each area, with the lines of magnetic flux during the second application at approximately 90° to the lines of magnetic flux in the first application. Depending on the shape of the part and its location at the time of inspection, magnetization can be done by passing a current through the part or by an encircling coil and sometimes by a magnetic yoke. The acceptance level is judged by a qualified operator and is subject to review by an authorized code inspector.

Liquid penetrant inspection is usually employed on nonferromagnetic alloys, such as some stainless steels and high-nickel alloys. The acceptance standards are the same as for magnetic particle inspection and are also judged by an operator, subject to review by a code inspector. The methods are specified to those contained in ASTM E 165 (Ref 5) or section V of the ASME code. Water-washable, postemulsifiable, or solvent-removable penetrants can be used. A water-washable color-contrast penetrant is usually employed because it is easy to handle, requires no special ventilation, and is nontoxic. Sometimes, special requirements dictate the use of either a solvent-removable color-contrast penetrant or a fluorescent penetrant.

Ultrasonic inspection is used to inspect piping, pressure vessels, turbine rotors, and reactor coolant pump shafts. Straight-beam ultrasonic inspection is specified to detect laminations in plates and to detect discontinuities in welds and forgings. This technique is described in general and specific terms in section XI of the ASME code, in the United States Nuclear Regulatory Commission Regulatory Guide 1.150 (Ultrasonic Testing of Reactor Vessel Welds During Preservice and Inservice Examinations), and in companion reports written by utility *ad hoc* committees (Ref, 1). Angle-beam inspection is specified for welds, and a more detailed procedure is presented, including reporting requirements. It is mandatory, however, that ultrasonic inspection, either by straight beam or angle beam, be conducted to a detailed written procedure. These procedures are usually developed by the manufacturer. Specifications and standards for steel pressure vessels are given in ASTM A 577 (Ref 6), A 578 (Ref 7), and A 435 (Ref 8). Acceptance standards for the inspection of welds by ultrasonics closely parallel the acceptance standards for radiography. Cracks, incomplete fusion, and incomplete penetration are not permitted. The size permitted for other linear indications is the same for the slag permitted by radiography. However, ultrasonic inspection can detect cracks better than radiography, but it is sometimes difficult to separate cracks from other linear indications by ultrasonics. Furthermore, ultrasonic inspection procedures refer to the amplitude of the signal obtained from a calibration notch, hole, or reflector placed in a standard reference block, but not all slag inclusions or cracks in an actual workpiece present a similar response to that obtained from the artificial calibrator.

Advanced ultrasonic systems (see the section "In-Service Quantitative Evaluation" in this article) and the improvements in codes and regulations have combined to make ultrasonic inspection one of the most commonly used nondestructive methods in the power industry. Advanced ultrasonic methods are intended to ensure that the vessel remains fit for continued service by detecting and sizing defects that could degrade structural integrity.

Acoustic emission (AE) inspection has been used for the following applications (Ref 9):

- Inspection of chemical and petrochemical vessels
- Monitoring nuclear plant components or systems during hydrotests, plant operation, or preservice pressure testing of the primary system
- Monitoring during pressure testing of intentionally flawed vessels

- Monitoring fiber-reinforced plastic tanks, with the major problems being associated with poor manufacturing techniques that allow dust and other foreign objects to be mixed in with the resin
- Monitoring liquefied petroleum gas storage tanks. The main problems associated with this type of test program include the different propagation paths and attenuation coefficients caused by the geometry of the vessel and the correct transducer locations and spacing

Rupture tests on experimental vessels with wall thicknesses up to 150 mm (6 in.) have been monitored, and such tests help define the acoustic emission response patterns that can be used to recognize incipient vessel failures. However, many of the vessel rupture tests monitored by acoustic emission have been conducted mainly to provide fracture mechanics data, and the acoustic emission monitoring was an add-on feature (Ref 9).

Acoustic emission tests are often conducted during preshutdown operations in an effort to identify areas requiring special maintenance or during special tests while under slightly varied operational conditions. Data on wave propagation and failure mechanisms have been recorded and used to develop reliable acoustic emission evaluation techniques (Ref 10).

The advancement of AE inspection techniques includes the introduction of an AE methodology into Section V, Article 12, of the ASME Boiler and Pressure Vessel Code as a December 1988 Addendum. Other AE methodologies in the inspection of fiber-glass and metal pressure vessels are described in the article "Acoustic Emission Inspection" in this Volume.

Eddy Current Inspection. One of the rapidly increasing applications for this method is the inspection of thin-wall (0.9 to 1.5 mm, or 0.035 to 0.060 in.) Inconel alloy steam generator tubing (Ref 11, 12) and heat exchanger tubing (Ref 13). The focus of steam generator tube inspection by eddy current has shifted from concentrating solely on the detection and characterization of tube wall denting and wastage to more complex tube wall degradation mechanisms. The newer degradation mechanisms consist of intergranular attack (IGA), stress-corrosion cracking (SCC), mechanical wear, and pitting in the presence of copper. A summary of steam generator tubing defects is shown in Fig. 1. In response to the complexity of these newer problems, eddy current instrumentation has also evolved from a single-frequency to a multiple-frequency configuration. The analog instrumentation has been replaced by digital multiple-frequency instrumentation, offering more consistent data acquisition. The wider dynamic range offered by the digital instrumentation allows analysis of eddy current data obtained from traditionally difficult areas, such as dented tube support/tube sheet interfaces and roll transition/roll expansion areas within the tube sheet. Additional information, including typical data produced by multiple-frequency instrumentation, can be found in the article "Eddy Current Inspection" in this Volume.

Fig. 1 Locations of known tube wall degradations in recirculating steam generators. Source: Ref 11

Another advancement is that of remote-field eddy current testing, which has been used to examine nuclear fuel rods and other tubular products. The article "Remote-Field Eddy Current Inspection" in this Volume can be consulted for details and results of analyses.

Replication microscopy, or field metallography, is an effective and economical means of obtaining an image of a component surface, permitting both on-site and laboratory examination and evaluation of the metallurgical condition of the material (see the article "Replication Microscopy Techniques for NDE" in this Volume). Material sample removal from critical components is a costly and time-consuming process that often necessitates part replacement, weld repair, and stress relief. The replication examination is completed without having to cut out a portion of the component, and the metallurgical data can be determined in fine detail. Therefore, material evaluation can be performed with a nondestructive and cost-effective method that does not require the removal of material samples.

Specimen (Surface) Preparation. Critical surface locations for inspection are identified, and external insulation is removed. The area to be replicated is polished with progressively finer grits and compounds. The final compound is a 0.25 μm diamond polishing paste, which ensures a surface finish of 1 μm or better.

The surface is then etched to reveal the microstructural detail (Fig. 2). A plastic film is applied, cured, and carefully removed. The surface of the film in contact with the polished area retains a precise, reverse image of the etched component surface.

Fig. 2 Weld microstructures showing no evidence of microvoids in a secondary superheater outlet header made from 1.25Cr-0.5Mo steel. (a) Weld metal. (b) Heat-affected zone. (c) Base metal. Weld location: nozzle-to-header weld (header side of weld). All 400 \times . Courtesy of H.I. Newton, Babcock & Wilcox

Procedure/Defect Analysis. In the laboratory, the replica is examined using standard light (optical) microscopy, or it can be viewed at high magnification with an electron microscope. To improve resolution, the replica is enhanced by shadowing with sputtering or vacuum evaporation techniques.

An actual replica magnified to 400 \times is shown in Fig. 3. The microstructure indicates that linked creep voids exist along the grain boundaries in this component, suggesting that creep is active and that cracking is imminent. The progression of damage from microstructural voiding to linked voids to cracking is schematically illustrated in Fig. 4. Replicas can reveal all the microvoids, microcracks, and microstructural features in exact detail, just as if the metal surface itself were being viewed.

Fig. 3 Replica showing random and linked microvoids in the heat-affected zone of a secondary superheater outlet header weld. 400 \times . Courtesy of H.I. Newton, Babcock & Wilcox

Fig. 4 Progression of creep damage over time as depicted by replica photomicrographs. Courtesy of H.I. Newton, Babcock & Wilcox

The principal application of the replication technique is in revealing metallurgical anomalies and incipient damage (cracking). In the absence of fatigue and/or preexisting defects, creep cracks are theorized to initiate by the formation, growth, and linkup of voids into microcracks, which in turn consolidate to form macrocracks (Fig. 5). The propagation of the macrocracks can then lead to final failure.

Fig. 5 Replicas of creep damage in pressure vessel components. (a) Random and linked microvoids in a 1.25Cr-0.5Mo main steam line weld. 425 \times . Courtesy of H.I. Newton, Babcock & Wilcox. (b) and (c) A comparison of scanning electron micrographs of a replica from 1.25Cr-0.5Mo material with aligned creep cavities. (b) Normal contrast. (c) Reversed image contrast. Etched with 4% picral. Courtesy of E.V. Sullivan, Aptech Engineering Services, Inc.

In actuality, a creep-fatigue interaction better describes the type of damage mechanism most often encountered. It is theorized that the creep mechanism described previously is accomplished by a fatigue mechanism. In a creep-fatigue interaction, one may observe a mixture of intergranular and transgranular crack growth surfaces with the absence of voiding. The presence of preexisting flaws affords an initiation site for cracking and subsequent material degradation.

Actively growing cracks are evidence that the condition of a component is deteriorating under service loads; this warrants monitoring, repair, or replacement. Creep-fatigue interaction is discussed in detail in the article "Creep-Fatigue Interaction" in *Mechanical Testing*, Volume 8 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*.

The advantages of the replication techniques are many. It is nondestructive. An accurate image of the component surface is also obtained. In addition, early detection of damage and the evaluation of existing failure mechanisms are possible. Replicas also reinforce decision making with regard to the need to replace or repair critical degraded components.

Limitations. There are also disadvantages with the replication technique. The analysis is limited to the accessible surface of the component. The replication technique is also site sensitive. In addition, no compositional analysis of the microstructural constituents is possible with surface replicas, although extraction replicas have been used in chemical analysis (see the section "Precipitate Analysis" in the article "Replication Microscopy Techniques for NDE" in this Volume). With these limitations in mind, it is recommended that replication be used in conjunction with other nondestructive techniques to provide a complete overall evaluation of a component.

Inspection of Plates, Forgings, and Tubes

Plates up to 300 mm (12 in.) thick, such as those conforming to ASME SA-533, grade B (Fe-Mn-Ni-Mo) are used for pressure vessel shell sections. All plates are ultrasonically inspected 100%. Pulse-echo search units have been adapted for this inspection. The search unit consists of an immersion-type longitudinal wave or shear wave transducer encased in a container holding a liquid couplant. Because the container can conform to minor surface irregularities on the material being inspected, much of the surface conditioning previously required for contact inspection is eliminated. Good, sound penetration and a stable back reflection are obtained with this type of unit.

Straight-beam inspection is conducted over the entire surface of the plate. Calibration for straight-beam inspection is accomplished by adjusting the back-reflection amplitude from the opposite surface to approximately 75% of the height of the CRT. Discontinuities causing a loss of back reflection that cannot be contained in a 75 mm (3 in.) diam circle are unacceptable. Laminar-type discontinuities, which are the most common type of imperfections encountered in plate materials, are readily detected by straight-beam inspection.

The angle-beam inspection of plates is included in many specifications. Scanning is conducted in overlapping passes over the entire surface in two directions at 90° to each other. Calibration is accomplished by adjusting the signal to a square notch milled to a depth of 3% of the plate thickness. Discontinuity indications equal to or exceeding the signal amplitude from the notch are cause for rejection.

During the ultrasonic inspection of plates, close attention must be given to signal patterns that indicate the presence of discontinuities, such as secondary piping, which do not normally produce significant response indications on the oscilloscope. Discontinuities of this type can result in untimely rejection or high rework costs if not detected prior to the start of fabrication.

Forgings used for pressure vessel flanges, head flanges, and nozzles are commonly purchased to the requirements of ASME specifications, such as those of ASME SA-508, class 2 (Fe-Mn-Ni-Cr-Mo-V), and are heat treated and nondestructively inspected by the supplier. Ultrasonic inspection is required on two surfaces of the forging using the straight-beam inspection method; for ring or hollow round shapes, angle-beam inspection is specified. These inspections must be carried out prior to contour machining to ensure complete volumetric coverage. Inspection is repeated to the maximum extent practical after machining and heat treatment are completed. Discontinuity indications observed by straight-beam inspection that cause a loss of back reflection, and by angle-beam inspection that are equal to a 3%-of-plate-thickness notch, will result in the rejection of the component.

Ferromagnetic forgings are inspected by magnetic particle inspection methods after final heat treatment and contour machining. Linear discontinuities such as laps, cracks, or inclusions are cause for rejection.

Tubular products can receive ultrasonic and liquid penetrant inspections prior to release for fabrication. As stated above, eddy current inspection is common during the in-service inspection of tubular products.

Nondestructive Inspection of Boilers and Pressure Vessels

Nondestructive Inspection During Fabrication

Plates are formed into shell cylinder segments or into hemispherical segments for the top and bottom heads. Shell plates of thick material are hot formed by pressing to the radius required. Plates for head segments are hot formed over dies machined to the proper contour. After the hot forming is completed, the plates are allowed to cool and are then inspected to confirm that the proper radius has been obtained. The formed section is then reheated, water quenched, and tempered to obtain the required mechanical properties. Samples are cut from the heat-treated material and tested to determine the tensile and impact properties of the material before further fabrication is permitted.

Fit-Up and Welding. Edges of plates that are machined in preparation for welding are magnetic particle inspected. Surface discontinuities, other than laminar types less than 25 mm (1 in.) long, are removed. Discontinuities with any significant thickness are further investigated by radiographic or ultrasonic inspection to determine their nature and extent.

Welding of the longitudinal seams in the shell cylinders is commonly performed by the multilayer submerged arc process. Single arc and tandem arc procedures are used, with preheating and postheating when specified. Welding of head-torus sections can be done using the horizontal submerged arc process, in which the weld beads are deposited through the thickness of the material. With the horizontal submerged arc process, the axis of the weld is in a vertical position, and each weld bead is deposited from the inside to the outside of the seam progressively upward until the complete length is welded. A manual welding procedure (usually, shielded metal arc) in which the axis of the weld is in the vertical position is sometimes used instead of the submerged arc process. These processes require NDI techniques suitable for adequate interpretation of discontinuity size. After welding and interstage stress relieving of the longitudinal seams are completed, the weld is magnetic particle inspected and radiographed.

The design of the weld joint and the welding procedure used are important considerations in determining the extent of nondestructive inspection and the adequacy of the results. The narrow-groove weld joint illustrated in Fig. 6 provides for good radio-graphic inspection, including crack detection. Those cracks that are more likely to occur along the sidewall of a weld are essentially parallel to the radiographic beam in the joint design. When the radiographs are made with equipment and techniques that obtain good sensitivity in these thick-section welds, cracks of this type can be readily detected. Welds having wide-angle sidewalls require additional angle radiography or ultrasonic inspection.

Fig. 6 Sequence of assembly and typical narrow-groove joint used for the welding of thick plates in pressure vessels

The depth at which slag inclusions are beneath the surface and the thickness of the inclusions usually cannot be determined by radiographs taken normal to the weld surface. Discontinuity indications observed on the film usually require additional angle radiography or ultrasonic inspection to determine the depth and thickness of the slag inclusions. Acceptance standards for welds made in the vertical position are more rigid than acceptance standards applied to other welding procedures.

Clad Vessels. Certain types of pressure vessels, such as some nuclear vessels or chemical-processing vessels, are fabricated from carbon or alloy steels whose inside surfaces are clad with a layer of stainless steel. With these types of vessels, the inner surfaces are machined smooth to provide a suitable surface for cladding. Machining is done after the shell and head-torus subassemblies have been completed. After machining, the smoothed surfaces are magnetic particle inspected; no indications of linear discontinuities are permitted.

Also at this manufacturing stage, the formed and heat-treated material is again ultrasonically inspected. This inspection is performed using the straight-beam method over the entire surface of the material. Changes in the acoustic quality of the material as a result of heat treatment may cause minor differences in the signal amplitude from those indications previously recorded.

The inner surfaces of large pressure vessels are clad, oscillating multiple-wire systems or strip electrodes. Three-wire and six-wire self-shielded flux-cored wire, plasma arc processes, and electroslag overlays are also used for pressure vessel applications.

Liquid penetrant inspection is performed on all clad surfaces. When properly cleaned, the as-deposited clad surface is adequate for liquid penetrant inspection. Solvent-removable red-dye penetrants are often used for this inspection.

Acceptance standards do not allow linear indications of any type. Rounded indications with less than 1.5 mm ($\frac{1}{16}$ in.) maximum dimension are acceptable. Mating surfaces of machined flanges and surfaces of O-ring seals are inspected to more rigid acceptance standards. Sealing surfaces must be free of any indications.

Calibration for inspection of the cladding is accomplished by setting up the inspection equipment on a reference block clad by the same process as the material being inspected. A 10 mm ($\frac{1}{3}$ in.) wide slot is machined through the backing material to the cladding interface. The ultrasonic pattern observed from the slot in the reference block provides the acceptance standard for the cladding.

Inspections are conducted from the clad side of the material, except for small-diameter nozzles. When inspecting from the side opposite the cladding, close observation must be given to the presence of laminar discontinuities in the base material that could mask the area of inspection. Cladding on mating flange surfaces is inspected to a more rigid standard by pitch-catch echo testing. The two-transducer system is calibrated on a 1.5 mm ($\frac{1}{16}$ in.) diam, side-drilled hole at the interface of the cladding and base material. Discontinuity indications exceeding the amplitude of the signal from the calibration hole are unacceptable.

Assembly. Shell cylinders and flanges are joined together by welding the girth seams using the submerged arc process. Back grooves, final surfaces, and surfaces prepared for welding are magnetic particle inspected. Radiography is performed after cladding the inside of the welded girth seam.

Nozzle openings are cut in the shell cylinder and are then machined to the size and shape required for fitting the nozzles. The narrow-groove weld joint, through the shell thickness, is used for the nozzle-to-shell weld.

Nozzle welds are made by either the manual or the automatic submerged arc process. In addition to magnetic particle and radiographic inspection, all nozzle welds are subjected to ultrasonic inspection. The techniques for the ultrasonic inspection of welds contained in the ASME code are used as the basic method of inspection. Angle-beam inspection is performed on the outer surface of the shell adjacent to the nozzle weld. The sound beam is aimed about 90° to the weld and manipulated laterally and longitudinally so that maximum coverage is obtained.

Sound-beam dispersion from the effect of the clad interface prevents full-node sound transmission. Only the discontinuities encountered in the initial sound path through the material can be consistently detected by the angle beam. Straight-beam inspection is performed by directing the sound into the weld from the inside of the nozzle. The combination of straight-beam and angle-beam inspection provides full inspection coverage of the weld.

For the detection of cracks in welds, ultrasonics and radiography have complementary advantages and disadvantages. Vertical, subsurface cracks in a weld that are readily detectable by radiographic methods are extremely difficult to detect by ultrasonics. Discontinuities oriented in a plane other than normal to the weld surface can be best detected ultrasonically.

Various beam angles and frequencies are used to establish the best ultrasonic procedure that could be applied to production welds. The standard 45° transducer at a frequency of 2.25 MHz is commonly used for the detection of cracks. However, to provide additional assurance, scanning should be performed at a gain setting of at least ten times the calibration sensitivity.

Final Inspection. After assembly is completed and all inspections are verified, the vessel is subjected to a final stress-relieving treatment. Magnetic particle inspection of all exposed ferritic material is again performed, using the yoke method. Arc strikes that are likely to occur with the prod method are thus avoided on the final stress-relieved surface.

Final machining of the vessel and head is done after stress relieving. All machined surfaces are inspected by liquid penetrants after the vessel is dimensionally inspected.

Vessel and head inside surfaces are thoroughly cleaned, and the vessel is positioned vertically for hydrostatic testing. After hydrostatic testing, all exposed ferritic welds are magnetic particle inspected. Instrumentation and attachment welds are liquid penetrant inspected.

A baseline ultrasonic inspection can be performed on the completed vessel. This inspection provides a record of ultrasonic indications that can be used as a reference for future in-service inspections of the vessel. The data generated from this inspection are useful only if the method of inspection during the in-service inspection is compatible with the baseline inspection method. The effect of the cladding interface on the ultrasonic sound beam requires increased sensitivity settings on the equipment if inspection is conducted from the inside of the vessel. Beam-angle changes due to the irregular cladding interface require exact duplication of the position of the transducer and the entrance angle of the sound beam if reproducible results are to be obtained. Equipment capable of remotely controlling these variables is essential if these inspections are to be conducted.

Nondestructive Inspection of Boilers and Pressure Vessels

Visual Inspection of Pressure Vessels

Visual inspection can readily detect misalignment, movement of mating parts, surface contamination, cracks, and other surface discontinuities. Direct examination is possible when the eye or an equivalent detector can be placed within 600 mm (24 in.) of the surface to be inspected. Where radiation levels are too high or access is limited, remote inspections can be used; telescopes, periscopes, borescopes, fiber optics, or television monitoring systems are available (see the article "Visual Inspection" in this Volume).

Visual inspection requirements are extensive in section XI of the ASME Boiler and Pressure Vessel Code. In general, all weld areas not receiving volumetric inspections must be visually inspected after hydrostatic testing. Also, comprehensive inspections are applied to bolting, piping, pumps, and valves.

Nondestructive Inspection of Boilers and Pressure Vessels

Radiographic Inspection of Pressure Vessels

A radiograph is basically a two-dimensional picture of the intensity distribution of a form of radiation that is projected from a source (ideally, a point source) and that has passed through a material that attenuates the intensity of the radiation. Voids, changes in thickness, or regions of different composition will, under favorable circumstances, attenuate the radiation by different amounts, producing a projected shadow of themselves. Three forms of penetrating radiation are used in radiography: x-rays, γ -rays, and neutrons. X-rays were the earliest to be used. Detailed information on radiography is available in the article "Radiographic Inspection" in this Volume.

Radiography is normally used to examine welded seams in fabricated pressure vessels. The main reasons for the use of radiography are the following:

- Radiography permits internal inspection of a component
- Radiography supplies a permanent visual record
- Radiography is generally sensitive to discontinuities commonly present in welds

The use of radiography is generally restricted to the inspection of welds for the following reasons:

- The cost of performing radiographic inspections is high when compared to other available methods
- Radiographic inspection of large areas is relatively slow
- Radiography is insensitive to laminar-type discontinuities

Radiography can be used, if the proper equipment is available, to inspect welds in steel pressure vessels with walls up to 400 mm (16 in.) thick. The only conditions that could limit the use of radiography for the inspection of welds in pressure vessels are, first, a lack of accessibility to both sides of the weld for placement of the film and the radiation source and, second, a high degree of variability in shape and thickness in the area being inspected. Both single-wall and double-wall techniques are commonly employed for the radiographic inspection of pipe. Detailed discussions of these techniques are available in the article "Radiographic Inspection" in this Volume. The following examples describe standard radiographic techniques used to inspect common welded seams in pressure vessels.

Example 1: Radiographic Inspection of Longitudinal, Girth, and Nozzle Welds in a Carbon Steel Pressure Vessel.

The pressure vessel shown in Fig. 7 was used in a commercial nuclear application and was inspected in accordance with section III of the ASME Boiler and Pressure Vessel Code. The material was 65 mm ($2\frac{1}{2}$ in.) thick carbon steel. The weld joints were single-V grooves and were welded using the submerged arc process for both the longitudinal and girth seams. Shielded metal arc welding was used to join the nozzle to the vessel.

Fig. 7 Nuclear pressure vessel, of 65 mm ($2\frac{1}{2}$ in.) thick carbon steel, in which longitudinal, girth, and nozzle welds were radiographically inspected using 50-Ci cobalt-60 as the radiation source, Eastman Kodak type AA radiographic film, and the inspection setups shown. Dimensions given in inches

For radiographic inspection, cobalt-60 was selected as the radiation inspection because of the thickness of the material, and Eastman Kodak type AA film was selected for its relative speed to give the shortest exposure time. The combination of Co-60 and type AA film can sometimes result in marginal sensitivity that occasionally requires the reshooting of a specific region.

Each longitudinal seam was radiographically inspected with eight shots spaced 350 mm (14 in.) apart using a 180 × 430 mm (7 × 17 in.) film. The penetrameters were steel ASTM No. 45 with a 1.5 mm ($\frac{1}{16}$ in.) thick shim. The Co-60 radiation source was placed 690 mm (27 in.) from the film. The cassette was loaded with a 0.25 mm (0.010 in.) thick lead screen, two pieces of film, a 0.25 mm (0.010 in.) thick lead screen, and a 3 mm ($\frac{1}{8}$ in.) thick lead back shield. Section A-A in Fig. 7 shows the setup for radiographic inspection of the longitudinal seam.

The girth weld was inspected using the panoramic technique, in which the Co-60, 50-Ci radiation source was placed at the center of the vessel and 28 film cassettes were placed around the outer surface (section B-B, Fig. 7). The technique involves only one exposure of 25 min to radiograph the entire seam, but its success depends on the placement of the radiation source exactly in the center of the vessel. The disadvantages of this technique include a lengthy setup time, a fairly complicated setup, and additional film costs if an error is made.

An alternative technique is to place the radiation source outside the vessel and inspect the seam with 28 separate exposures. This method would result in higher-quality radiographs, but a much longer total exposure time would be required.

Three equally spaced steel ASTM No. 45 penetrameters with 1.5 mm ($\frac{1}{16}$ in.) thick shims were used for the 28 radiographs. The film size and the types and thicknesses of screens and filters were the same as those used for the longitudinal seam welds.

The nozzle seam weld was radiographed using eight 13-min exposures. As shown in section C-C in Fig. 7, the radiation source was placed outside the vessel and was offset at an angle of 7 to 10° away from the nozzle. The source-to-film distance was 900 mm (36 in.). The variation in weld thickness at the nozzle required that two penetrameters be used. One was flush to the sidewall, and the other had a 9 mm ($\frac{3}{8}$ in.) thick shim, which compensated for the difference in weld thickness. This two-penetrometer setup qualified the sensitivity of the radiograph because of the differential thickness of the weld being inspected. A sensitivity of 2-2T and a density of 2.0 were specified for the radiographs of all three types of welds.

Example 2: Radiographic Inspection for Creep Fissures in Reformer-Furnace Tubes

(Ref 14). About 1 year after start-up, two steam-methane reformer furnaces were subjected to short-time heat excursions because of a power outage, which resulted in creep bulging in the Incoloy 800 outlet pigtails, requiring complete replacement. It was thought that during this heat excursion some of the reformer tubes experienced slight bulging, about 1%, by plastic deformation. However, this type of bulging does not necessarily shorten the life of a tube in terms of creep.

Each furnace had three cells, consisting of 112 vertical tubes per cell, each filled with a nickel catalyst. The tubes were centrifugally cast from ASTM A297, grade HK-40 (Fe-25Cr-20Ni-0.40C), heat-resistant alloy. The tubes had an outside diameter of 150 mm (5.85 in.) and a minimum wall thickness as-cast of 20 mm (0.802 in.), and they were more than 13.7 m (45 ft) in length. The design limits for the tubes were 2200 kPa (320 psi), with a surface temperature of 958 °C (1757 °F). Operating limits were 2140 kPa (310 psi) at a surface temperature of 943 °C (1730 °F). The furnace cell is illustrated in Fig. 8(a).

Fig. 8 Reformer-furnace cell from which cast tubes of ASTM A 297, HK-40, heat-resistant alloy were radiographically inspected for the detection of creep fissuring. (a) Schematic of furnace cell showing positions of radiographic sources and films. Dimensions given in inches. (b) Radiograph of a section removed from a failed tube that contained no catalyst showing fissures near the ruptured area. (c) Same section as (b) but containing a catalyst. Fissures are visible but less apparent. (d) Macrograph showing fissures in a tube that were detected by radiography. 6×. (e) Macrograph showing fine fissuring that was not indicated by radiography. 6×

The first tube failure occurred after 33,000 h of operation. The unit was shut down, and the failed tube was removed for metallurgical inspection. The results indicated that the tube failed from creep rupture (stress rupture). The tube failure instigated a project for detecting midwall creep fissuring. Radiography had been reported to be limited to detecting only severe third-stage creep and not the early stages.

Laboratory Radiography. Preliminary studies were made to determine type of radiation source and strength, radiation source-to-film distance, exposure time, and effect of catalyst in tube. Figure 8(b) shows a laboratory radiograph of a section removed from the failed tube without catalyst. Fissures were clearly visible near the ruptured area and diminished to nondetectable fissures at a point 400 mm (16 in.) below the rupture. The same tube section radiographed under similar conditions but with catalyst in the tube is shown in Fig. 8(c). Fissures are visible, but it is apparent that the catalyst reduced the sensitivity by masking the smaller fissures.

Liquid penetrant inspection and macroexamination of the specimen tube revealed the gross fissuring that was easily detectable and those fissures that were undetectable by radiography. The largest fissures undetectable by radiography were approximately 3 mm (0.125 in.) long and 0.13 mm (0.005 in.) wide. (Fissures have been detected that were between 5 and 10 mm, or 0.200 and 0.400 in., long.)

Based on the radiography and macroexamination results, it was decided that future tube replacements would be inspected by radiography, preferably with the catalyst removed. If the fissure were large enough to show on a radiograph, either with or without the catalyst, the tube could be expected to fail within 1 year.

In-Service Radiographic Inspection. During shutdown of one furnace, the first full test of the radiographic inspection method was made. All the tubes were measured for evidence of outside diameter growth, and the suspect areas

were strapped to identify the hottest zones. Growth to failure in HK-40 material having a rough exterior surface is difficult to measure, because total creep of only about 1% has occurred by the time of failure. Gaging did not show much, but strapping on some tubes clearly identified bulging in the hottest areas about 1.4 m (54 in.) above the burner terrace. This was used as the basis for radiographing all other tubes.

The catalyst was removed from the tubes in preparation for radiography. Two IR-192 radiation sources having a strength of 3300 GBq (90 Ci) and one 3700 GBq (100 Ci) source were used, mounted in jigs at distances of 750 and 900 mm (30 and 36 in.), respectively, from the film. A tungsten collimator was also used to limit the emission to a single tube and permit the technicians to remain in the firebox during exposure. Exposure time was 7 to 10 min per shot, and approximately 700 shots were taken.

Shortly after the first furnace was back on stream, the second furnace was shut down and the tubes radiographed. Using the same techniques but with a 3900 GBq (105 Ci) source, time to radiograph the second furnace was reduced about 25%.

Twenty-four tubes in the first furnace and 53 in the second furnace showed significant fissuring. One of these fissured tubes was left in the first furnace and 15 in the second; when these tubes eventually failed, they would provide an indication of remaining life after a known radiographic examination.

One of the tubes that had been removed from the furnace was sectioned at two places--through a radiographic indication of a fissure and through an area containing no indications. Macrographs of these sections are shown in Fig. 8(d) and 8(e). Figure 8(d) shows fissuring that was detected by radiography. Fine fissuring that was not seen on the radiograph is shown in Fig. 8(e).

Conclusion. Radiography was a practical, economical method of detecting the creep fissuring, and it provided advance information for purchase of replacement tubes. However, because radiography was limited to detecting fissures caused by third-stage creep in tubes from which the nickel catalyst had been removed and because of the cost of removing the catalyst, ultrasonic techniques were developed for inspecting the tubes. These techniques are described in Example 4 in this article.

Nondestructive Inspection of Boilers and Pressure Vessels

Ultrasonic Inspection of Pressure Vessels

Volumetric inspections are used to inspect the volume of material bounded by the surfaces of components and of piping. Theoretically, any source of energy that penetrates the volume of a material can be used. In practice, however, only x-rays, γ -rays, and ultrasonic waves are used. In nuclear vessels, which are housed in a containment building, radiographic inspection methods for in-service inspection currently have limited use because of the need for access to both surfaces and because of the high γ -ray background in most areas of the containment building. When radiography is used, other inspection methods such as acoustic emission can also be used for additional monitoring. However, a large number of inspections are performed using various ultrasonic techniques.

As described in the article "Ultrasonic Inspection" in this Volume, ultrasonic waves are generated by piezoelectric transducers that convert high-frequency electrical signals into mechanical vibrations. These mechanical vibrations form a wave front, which is coupled to the vessel being inspected through the use of a suitable medium. Several wave modes can be used for inspection, depending on the orientation and location of the discontinuities that exist. Longitudinal, shear, and surface waves are used separately in different techniques to reveal discontinuities that are respectively parallel to, at an angle to, and on or near the surface from which the inspection is performed. These inspections are made with longitudinal wave transducers, pulse-echo, through transmission, pitch-catch, or delta techniques. Most of the inspections are performed using pulse-echo straight longitudinal wave beams and angled shear wave beams from a single transducer.

Manual ultrasonic inspection is performed with single-transducer pulse-echo techniques. The ultrasonic wave is coupled to the component being inspected through a couplant (usually a glycerin or light oil) that transports the ultrasound between the face of the transducer and the surface of the component. In longitudinal wave straight-beam inspection, ultrasonic waves enter normal to the surface and will detect discontinuities perpendicular to the direction of wave propagation. In angle-beam inspection, the longitudinal wave is coupled through a plastic wedge at an angle to the surface. The wave is again coupled to the component (still a longitudinal wave) and undergoes a mode conversion to a shear wave. The angle of the resulting shear wave is dependent on the ratio of the combination of ultrasonic velocities in the plastic wedge and the metal component with the angle of the incident longitudinal wave in the plastic wedge. Shear wave angles from 40 to 75° are used for inspection. Indications are recorded and plotted from reference locations on the weld metal.

Automated Ultrasonic Inspection. For accurate inspections, immersion ultrasonic inspection provides the highest level of inspection speed, accuracy, and repeatability. The coupling of ultrasonic waves is done with much less variability in couplant thickness and transducer pressure than occurs in manual techniques. The immersion method permits automated scanning and digital recording of data with a high degree of precision and repeatability. Additional advanced automated methods are described below in the section "In-Service Quantitative Evaluation" in this article.

Thickness Measurements. Inspection should properly begin with thickness measurements of the shell, heads, nozzles, and piping. Well-documented inspection records are necessary to complete a satisfactory inspection. Records can indicate where to expect metal loss or corrosion on the component and therefore enable the suspect areas to be thoroughly inspected. A comparison of measurements obtained during previous inspections will determine the amount of loss and corrosion rates. Original or nominal thicknesses taken from specifications usually have tolerances too great to make them reliable in the determination of corrosion rates. Vessels having a history of minimal corrosion require only a moderate amount of inspection, while those having a high corrosion rate or history of attack must be more thoroughly inspected. Inspection experience and records provide the key to how much coverage should be given. If the vessel is open, the thickness measurements can be made from the internal surfaces at any location the inspector desires--an approach much more flexible than dependence on fixed corrosion-gaging points.

The distance between thickness measurements can vary depending on the coverage desired, but a sufficient number of readings should be obtained to ensure a correct determination of vessel condition (distances generally range from $\frac{1}{3}$ to 1 m). In determining repair areas or the size and location of a patch, a grid pattern laid out on the vessel can be useful.

Rough or badly pitted surfaces should have a small area ground smooth to permit the transducer to make good contact. Transducers having a rubber membrane as a protective facing contact better on mildly pitted surfaces because the rubber will tend to conform to the surface. Removal of loose scale or dirt by scraping or filing is often sufficient surface preparation.

It is not necessary to drill gage holes or use other destructive methods to determine wall thickness. Insulation, if present, must be removed at gage locations for external measurements, but the removal of insulation is not required if the measurements are to be taken from the inside.

Special couplants enable many external measurements to be taken while the vessel is operating at temperatures of 370 °C (700 °F) or higher. Corrections should be made for errors introduced by the high temperature. Table 1 lists several correction factors for ultrasonic thickness measurements in carbon steels at elevated temperatures. Additional information can be found in Ref 15.

Table 1 Correction factors for ultrasonic thickness measurements in carbon steels at elevated temperatures

Temperature		Measurement				Correction factor
		Ultrasonic		Micrometer		
°C	°F	mm	in.	mm	in.	

40	100	13.11	0.516	13.11	0.516	0
95	200	13.15	0.518	13.13	0.517	0.998
150	300	13.26	0.522	13.14	0.5175	0.991
205	400	13.33	0.525	13.15	0.518	0.987
260	500	13.36	0.526	13.16	0.5185	0.986
315	600	13.41	0.528	13.18	0.519	0.983
370	700	13.46	0.520	13.20	0.520	0.981

Source: Ref 15

Flaw detection prior to fabrication is usually concerned with the inspection of steel or alloy plates for internal laminations, segregates, and similar discontinuities because they can be quite harmful under certain operating conditions. For example, hydrogen blistering can occur at a lamination, and stress-corrosion cracking, fatigue, intergranular corrosion, and hydrogen embrittlement are often accelerated by such discontinuities.

For flaw detection, a continuous-scan method is often used, in which the transducer is carried on a rigid carriage and the ultrasound waves are coupled into the plate by a stream of water. In some applications, the plate can be immersed, which simplifies the operation. To eliminate some of the human errors, a flaw-alarm system is set up so that a flaw of predetermined size will trigger a warning of some kind.

For the inspection of a weld, the weld shape may be such that the use of longitudinal waves is impossible, and a flaw such as a crack at the fusion zone probably will not present enough reflective area to be detected from directly above it. Nozzles located in hemispherical heads present special problems, and special techniques must be used to ensure a thorough inspection. Using shear waves, the sound can be directed into a suspect area from almost any angle. Large-scale drawings of the suspect area are needed to lay out correct angles and distances for the transducers (Fig. 9). For components having a complicated design, a plastic model can be an aid to better visualization of the sound path and angles of reflection. Thought given to the best approach and techniques can save hours in inspection and can ensure proper coverage. Angle transducers of 45 and 60° will detect almost any weld discontinuity, particularly if both internal and external surfaces are available for inspection. If the internal surface is not available, the nozzle can be filled with water and a search unit lowered to the correct depth to inspect the weld. The search unit can be adjusted to any angle and turned from side to side while in use. A plastic wedge on the search unit can be used to direct the sound beam through the nozzle body. Correctly angled, the beam will be intercepted by any radial flaw in the nozzle body and can also reach the attachment weld on the far side. The wedge can be shaped on a test block duplicating a nozzle section, and the sound path can be determined by through transmission (one transducer transmitting the signal and another, placed opposite, receiving the signal).

Fig. 9 Typical layout used on large-scale drawings to determine transducer angles and distances for inspection of difficult-to-reach weld areas

Shear wave search units intended for inspection at high temperatures may have the plastic wedge made of a special heat-resistant material. Such materials usually increase attenuation, and calibration must be made at temperatures close to that of the surface of the part being inspected if detection of a flaw of given size is to be ensured.

Examples of Application. The use of ultrasonics in the detection of discontinuities in a pressure vessel is discussed in the following examples. Additional information on in-service inspection is presented in the following section of this article.

Example 3: Use of Ultrasonic Inspection to Detect Creep Rupture in Stainless Steel Headers of an Ammonia-Plant Reformer Furnace

(Ref 16). A leak was detected in one of the coils in the radiant section of a primary reformer furnace used in an ammonia plant. Furnace temperatures were reduced immediately, but it was necessary to continue firing of the furnace at about 540 to 595 °C (1000 to 1100 °F) for 16 h to reduce the catalyst. Subsequent shutdown inspection revealed that the bottom of one of seven outlet headers had ruptured, causing a section about 100 mm (4 in.) wide by 460 mm (18 in.) long to fall to the furnace floor. The outlet headers were 100 mm (4 in.) nominal diameter schedule 120 (11 mm, or 0.438 in., wall) pipe about 10 m (34 ft) long and were made of ASME SA-452, grade TP316H, stainless steel. In the absence of hot spots, the surface of the outer tube ranged from 845 to 855 °C (1550 to 1575 °F). The unit had been on stream about 29,000 h prior to failure.

To get the unit back in service quickly, a section about 1.4 m ($4\frac{1}{2}$ ft) in length was replaced. The amount of header metal replaced was based on results from both visual and liquid penetrant inspections of the outer surface of the header. The inner surface, where accessible, was also checked visually and by liquid penetrant inspection. The six other headers were inspected at selected locations, and no surface cracks were detected.

Investigation of the Removed Section. Metallographic examination of the 1.4 m ($4\frac{1}{2}$ ft) section of the header that had been removed revealed that it had failed as a result of intergranular fissuring and oxidation, commonly termed creep rupture. Severe intergranular fissuring was found throughout the cross section of the header sample. Primary cracking occurred intergranularly through the grain boundaries, typical of high-temperature fissuring. Close observation of the crack paths linking some of the larger fissures, however, did reveal local areas having grains that were much smaller than

those of the header metal. The presence of these very small grains could only be the result of cold deformation and subsequent recrystallization at elevated temperatures. Therefore, some plastic strain and cracking had occurred at temperatures well below the operating temperature, apparently as a result of thermal expansion and contraction stresses during startups and shutdowns, and then the cold-strained areas had recrystallized subsequently when they were reheated to the service temperature. Therefore, it follows that all of the fissuring did not take place during any one operating period. Also, the microstructure in the ruptured area gave the following evidence that the header metal had not been subjected to gross overheating in service:

- The header metal still had a general grain structure that would be classified as being of fine size, while severe grain coarsening would have occurred if the header metal had been heated at temperatures between 1095 and 1315 °C (2000 and 2400 °F)
- The microconstituents present in the grains would have been dissolved at grossly elevated temperatures and would have been of much finer size if they had subsequently precipitated out of solid solution during the final 16 h of firing at 595 °C (1100 °F) to reduce catalyst

It was concluded from this investigation of the ruptured area that the header had failed by conventional long-time creep rupture as a result of exposure to operating temperatures probably between 900 and 955 °C (1650 and 1750 °F), rather than by short-time exposure at grossly elevated temperatures. It was suspected that the furnace headers might not be as sound as the visual and liquid penetrant inspections of the surface metal had indicated; therefore, three ring sections from the removed 1.4 in ($4\frac{1}{2}$ ft) long header section were selected for further study. The sections were taken from the ruptured area (sample A), from a slightly bulged but nonruptured area (sample B), and from visually sound metal about 0.6 m (2 ft) from the rupture (sample C).

Inspection of the three samples revealed the presence of pinhead-size intergranular fissures throughout the cross sections of samples B and C (Fig. 10). This indicated that the header metal at these locations had been in an advanced stage of creep rupture even though the fissures or voids were of small size. Sample C had fewer pinhead voids than sample B. With continued service, the pinhead voids would have increased in number and grown in size and eventually would have linked up and caused failure. Generally, the microstructure of the inner surface of the header in the area of rupture (sample A, Fig. 10a) contained intergranular fissures (black areas), a relatively fine grain structure, precipitated microconstituents in the grains, and considerable amounts of carbides in the nonfissured grain boundaries. The presence of the carbides was evidence of carbon pickup in service.

Fig. 10 Unetched microscopic appearance of three samples of failed pipe from a reformer-furnace header of TP316H stainless steel pipe and corresponding ultrasound responses of the three samples compared to the response of unused pipe. Micrographs of (a) sample A, (b) sample B, and (c) sample C. All 100 \times . Black voids are intergranular fissures. Ultrasound responses for (d) unused pipe, (e) sample C, (f) sample B, and (g) sample A. Strong reflections were obtained from the unused pipe, and attenuation increased as the number of fissures increased in damaged pipes.

Sample C had been removed from a visually undamaged header area located about 0.6 m (2 ft) from the rupture and about 250 mm (10 in.) from the sound end of the header section. It was considered possible that the header metal that was in service and only 250 mm (10 in.) away from the area of sample C was also in an advanced stage of creep rupture. It appeared probable that localized areas of the other six headers were in critical condition or that the problem was of a general nature. Therefore, it was decided that the remaining headers in service should be inspected as soon as possible because obtaining replacement parts might require several months of lead time. An ultrasonic attenuation method was considered to be the only possible nondestructive method for this evaluation, and development of a suitable system for use in the field was undertaken.

Ultrasonic Inspection Equipment and Standards. It was determined that optimum results that permitted the determination of changes in attenuation as a function of the number of cracks present required the use of a 22-MHz search unit in conjunction with a pulse-echo instrument. To minimize surface effects and curvature, a short water column was used to couple the sonic energy to the headers. This water column was enclosed in a Lucite cylinder 32 mm (1.25 in.) long with a 6 mm (0.25 in.) thick polyurethane-foam gasket at the bottom. The pliable gasket conformed to the curved

surfaces of the header. The search unit was held in position by a setscrew. Water flowed through the unit by gravity and escaped through a small hole in the Lucite cylinder at a point just above the front surface of the transducer.

A section of unused type 316H stainless steel pipe and the three sections of header metal from the rupture area were used for reference. Strong reflections were obtained from the undamaged pipe (Fig. 10); increased attenuation was obtained from damaged piping as the number of cracks increased, as indicated by the ultrasonic responses in Fig. 10(e) to 10(g).

The results of the test correlated well with the characterization of the number of cracks observed by optical microscopy (Fig. 10a to 10c). Approximately 1 year later, with 37,336 h on stream, the plant was shut down, and in-service inspection was conducted using the ultrasonic technique developed.

In-Service Ultrasonic Inspection. The standards and equipment used to develop the ultrasonic technique were used for the field inspection of the reformer furnace. Ultrasonic readings were taken on the horizontal header metal between each vertical tube and on both sides of any header welds. Over 350 readings were made. In addition, at some locations, readings were taken on the top, bottom, and sides. It was found that the headers all contained internal voids throughout their lengths, of varying numbers between those of samples B and C. The inspection results indicated that all headers were in an advanced stage of creep rupture (stress rupture) but that no areas had fissured to a degree that they needed immediate replacement. The replacement piping that had been installed during the previous shutdown 13 months earlier gave a "good" signal similar to unused material. The technique developed for the field survey was not adaptable for determining the conditions of the welded joints, so none of the readings represents welds.

On the basis of results of the in-service inspection, two conclusions were reached. First, the furnace was deemed serviceable, and second, in the absence of local hot spots, the headers would survive for a reasonable period of time.

Example 4: Ultrasonic Inspection for Creep Fissures in Reformer-Furnace Tubes

(Ref 17). Preliminary studies were made to establish whether sound would transmit through cast heat-resistant alloy HK-40 tubes from a reformer furnace. Several tests were conducted, and the most likely method was found to be the measurement of attenuation losses in a dual sensor using the through transmission method in an immersion tank. The tests showed that sound would transmit in HK-40 tubes with the use of a low-frequency transducer. Also, the rough outer surface of a centrifugal casting was the significant factor, rather than poor transmission in the large-grain cast microstructure. Immersion methods minimized the surface roughness condition and provided sufficient acoustic energy in the tubes. A dual search unit, with a sending transducer and a receiving transducer to produce a refracted-angle sound beam, was the best means for passing sound through the tube and across the plane of fissure formation. The attenuation of this beam, measured by the receiver, was a measure of fissure density.

Figure 11 shows the results of ultrasonic C-scan amplitude recordings on three sample tubes in an immersion tank. By moving the dual search unit at a constant speed longitudinally along the tube and indexing at the end of each traverse, and continuously recording the received ultrasonic signal, attenuation patterns in fissured tubes were recorded. Sample tubes with known fissures showed that some or all of the sound transmission was interrupted, depending on the density of the fissures (compare Fig. 11a and 11b). Sample tubes with no fissures showed full sound transmission (Fig. 11c).

Fig. 11 Ultrasonic C-scan recording of three sample alloy HK-40 tubes from a steam-methane reformer furnace. (a) Severely fissured tube. (b) Tube with small fissures. (c) Tube with no fissures. Light areas represent sound attenuation (no through signal); black areas represent no sound attenuation (through signal).

Strip chart recordings of sound attenuation were made on sections of sample tubes. By evaluation of the strip charts, the tubes were categorized as to sound attenuation and a grading scale of 1 to 5 was arbitrarily established. A rating of 1 represented good sound transmission through unfissured tubes, and a rating of 5 represented little or no sound transmission through severely fissured tubes. Intermediate values represented various degrees of fissuring.

Field Tests. On the basis of the preliminary tests, a field unit was built for subsequent furnace inspections that could be clamped on a tube and mechanically operated. The basic principle of the field unit is shown in Fig. 12.

Fig. 12 Creep fissures in a centrifugally cast HK-40 reformer-furnace tube that are detectable by ultrasonic inspection and by radiography with nickel catalyst in tube. (a) Tube cross section. 0.45 \times . (b) Tube wall. 2.5 \times . (c) Enlargement of inside diameter portion of wall shown at bottom in (b). 7.5 \times

The first full plant test with the unit was conducted with catalyst in the tubes. At that time, the furnace had operated over 50,000 h. The unit was calibrated on sample tubes with known conditions. Two men were in the furnace with voice communications to a third man outside the furnace operating the supporting ultrasonic equipment. With the unit clamped to the tube, a single scan was made at the critical hot area at each level. Ultrasonic scanning time at each location was less than 30 s, during which the attenuation information was recorded on a strip chart for later interpretation. About 32 h was required to inspect the entire furnace.

The tubes were graded on the scale of 1 to 5 established during testing of the sample tubes. Of the 295 tubes tested, about 15% had ratings of 5. About 30% of these tubes were replaced; the remainder were left in the furnace for a time-to-failure test. Of the 15 known fissured tubes left in the furnace at the previous shutdown (see Example 2), only 3 showed severe creep fissures by ultrasonic inspection and were replaced. The remaining 12 tubes had ratings of 4.

Metallographic examination was made of specimens taken from the removed tubes to determine the reliability of the ultrasonic unit. Results indicated that the unit was so sensitive that it could detect mild third-stage creep (not detectable by radiography) as well as severe fissures (detectable by radiography). Because of the sensitivity of the unit, there was some difficulty in differentiating between mild and severe fissuring. Radiography with catalyst in the tubes can detect only the most severe creep fissures, but it was used as the basis on which tubes were replaced.

The tubes with indications of severe creep fissures (ratings of 5) were radiographed. Seven tubes showed definite fissures on the radiographs, even with catalyst in place. These seven tubes and seven additional tubes that showed questionable fissures were replaced. One of the known fissured tubes left in the furnace during the previous shutdown showed questionable fissures on the radiograph taken with catalyst and had an ultrasonic rating of 5. This tube was again allowed to remain in the furnace for a time-to-failure test. Metallographic features of a tube with severe creep fissures that had a

rating of 5 with the ultrasonic unit, subsequently confirmed with radiography (with catalyst in the tube), are shown in Fig. 12.

Conclusions. The ultrasonic unit is a good field inspection tool for centrifugally cast alloy HK-40 tubes. Further refinement of the device is necessary to discriminate between mild and severe fissures and thus eliminate the need for radiography to determine the most severe fissures.

An ultrasonic inspection system provides the following advantages:

- Higher speed
- Increased coverage at lower cost
- Increased sensitivity
- Need for fewer radiographs
- Elimination of the need for removal of catalyst to effect inspection

In addition, maintenance work need not be interrupted while inspection is in progress, as it must be for radiography.

Nondestructive Inspection of Boilers and Pressure Vessels

In-Service Quantitative Evaluation (Ref 18, 19, 20)

The structural integrity of the reactor pressure vessel receives considerable attention because the vessel is the primary containment for the reactor coolant. In the United States, periodic in-service examination of the vessel is performed according to section XI of the ASME Boiler and Pressure Vessel Code. Ultrasonic methods of quantitative nondestructive evaluation (NDE) are those most commonly used to accomplish in-service examinations. Nearly all of the examinations are performed with remote-controlled equipment. Many innovative devices and specialized ultrasonic techniques have been developed to examine components with complex geometry, which are often extremely difficult to access. Some of the more difficult areas to examine are the under-clad region nozzle inner radii, nozzle-to-shell welds, dissimilar-metal welds in the safe-ends, and seam welds in areas of complex shape (Ref 18).

Fracture mechanics is used to evaluate indications detected during in-service examinations. Accurate measurements of the sizes and locations of all defects are required. Furthermore, the probabilistic failure prediction methodology now being used requires additional information on the probability of detecting flaws with each NDE technique. These requirements are the driving force in the current trend toward additional regulatory requirements for the quantitative demonstration of NDE performance (Ref 18).

The probability of detection as a function of flaw size and the accuracy of flaw size measurement are the important characteristics of each NDE technique that are to be measured in performance demonstration (Ref 18). Much of the work to date in the area of performance demonstrations and quantitative NDE of pressure vessels has been carried out at the Electric Power Research Institute (EPRI). Some of the published EPRI work is contained in the extensive list of Selected

References found at the end of this article. Additional information on the principles of quantitative analysis can be found in the Section "Quantitative Nondestructive Evaluation" in this Volume.

In designing NDE performance demonstrations, both the examination sensitivity and the mechanical precision of the scanning device must be addressed to determine if they are adequate to detect and size the defects of concern (Ref 18). Accordingly, the scope of a demonstration can be broken into three conveniently separate parts:

- The mechanical handling system
- The ultrasonic system
- The data-recording system

Mechanical Handling (Ref 18). The intent of testing the mechanical system is to measure and document the accuracy, backlash, and repeatability of the complete remote positioning system over its full range of operation. The tolerances of the mechanical system, when combined with those of the ultrasonic system, must give adequate flaw sizing and location capability for any required fracture mechanics analysis.

Tests of Ultrasonic and Data-Recording Systems (Ref 18). The intent of these tests is to demonstrate that the intended inspection procedures are capable of detecting and sizing all flaws of potential concern to the safety of the reactor pressure vessel. The vessel regions to be addressed can be categorized as follows:

- The region of the vessel in the vicinity of the cladding/base metal interface
- The nozzle regions, including nozzle inner radius, nozzle-to-vessel welds, and safe-end welds (up to and including the pipe-to-safe-end weld)
- The remaining welds that can be further categorized as circumferential or longitudinal welds. These are separately identified because of the different relative directions of weld, cladding, and curvature

Full-sized specimens representing the appropriate component are required. Intentional flaws are introduced of the size and type of concern. For example, these may be thermal fatigue cracks in the nozzle inner radius or intergranular stress-corrosion cracks in the nozzle-to-safe-end weld. The number of defects required in the demonstration is dependent on the purpose of that demonstration. Tests can be classified as either performance demonstration or validation. Additional information can be found in Ref 18 and in the Selected References that follow this article.

NDE of Clad Vessels (Ref 19). In the early 1980s, there was much concern in the United States about pressurized thermal shock, a series of events that started with a considerable primary fluid loss, the addition of cold make-up water, and the subsequent repressurization of the system. Under these conditions, small cracks (6 mm, or 0.25 in., in depth), if present immediately under the stainless steel vessel clad, could act as initiation sites for crack growth. This concern caused many reactor pressure vessel inspection development efforts to be focused on the detection of small cracks in the innermost region of the vessel inner surface. The following sections discuss several advanced systems developed at EPRI for the detection and sizing of flaws, the automatic discrimination of flaw signals, and computer-aided sizing from signals using crack tip diffraction methods.

The ultrasonic data recording and processing system (UDRPS) is a high-speed, general-purpose device that consists of a large minicomputer, high-speed data channel processor, color video display, and disk/tape storage devices. The UDRPS uses a detection criterion that is based on the signal-to-local-noise ratio threshold and the apparent motion of the target within the field of view of the moving transducer. Resulting patterns of indications are color coded for signal-to-noise ratio and are viewed by an analyst for the presence of formations suggestive of defects. Crack length and depth are also estimated from several image display modes that are available to the operator. Figure 13 shows the UDRPS results on a test block. Crack length and depth measurement capabilities are shown in Fig. 14.

Flaw discriminators provide the ability to distinguish among ultrasonic signal types. Feasibility studies have been conducted to demonstrate the use of integrated ultrasonic inspection and pattern recognition systems for distinguishing among slag inclusions, cracks, and spurious clad-noise signals.

Pressure Vessel Imaging Systems. The present inspection method for weld zones of nuclear reactor pressure vessels uses a pulse-echo ultrasonic technique for both preservice and in-service inspections. Pulse-echo inspection data are not sufficiently accurate to satisfy the demands of structural analysis by fracture mechanics methods. This has resulted in the development of imaging systems that combine conventional ultrasonic inspection techniques (B-scan, C-scan, pulse echo) with acoustic holography, which provides real-time three-dimensional estimations of flaw size and depth and more accurate information for fracture mechanics analysis.

Computer-aided sizing through crack tip diffraction involves the use of advanced digital processing methodologies that utilize spectral features of signals diffracted from the under-clad crack tips to distinguish more accurate depth estimates from less reliable ones. This technology is based on the development of sizing algorithms that are available as computer codes.

Nondestructive Inspection of Boilers and Pressure Vessels

Acoustic Emission Monitoring of Pressure Vessels

When discontinuities exist in a metal, a stress concentration occurs at the tips of discontinuities; under increasing applied stress, deformation occurs first at these discontinuities. This deformation, which may be plastic flow, microcracking, or even large-scale cracking, produces signals that, by means of suitable amplification, can be recorded as acoustic emission.

The emission is converted to an electrical signal by means of a piezoelectric transducer, which is mounted on the pressure vessel. The transducer is contained in a simple housing, which can be bonded to the vessel with glue or with a film of grease. The signal is then amplified (often using a preamplifier close to the transducer), filtered to remove low-frequency extraneous mechanical and electrical noise, and then recorded. Different types of analysis are used, and the signals can be shaped as pulses to aid quantitative interpretation of data.

Stressing of a discontinuity can produce a continuous emission and bursts of high amplitude. Analysis of these signals can be made in any of several ways; for example, each ring of the transducer above a set threshold can be counted or, alternatively, each high-amplitude burst can be counted as a discrete pulse. The number of counts per second or the integrated count is then compared with vessel pressure for strain.

Application. A series of search units is used for monitoring the emission of sound energy from stressed pressure vessels. All the outputs can be digitally stored for subsequent analysis. Additionally, some of the circuits can be continuously monitored to give an immediate indication of high acoustic activity and therefore the existence of a severe discontinuity that could cause fracture. Any source of acoustic emission can be located by measurement of the time taken for the signal

to reach different search units at known locations. On-line or subsequent location techniques can be used, preferably in conjunction with a small computer. The number of search units necessary depends on the degree of accuracy required in defining the sources of the emissions.

Most of the information in any signal generated from a source within a metal occurs in the 1 to 2 MHz frequency range; however, at these frequencies, the signal attenuation is high, so that the higher frequencies in the stress wave are soon attenuated to near the background noise over relatively short distances (a few meters). The lower-frequency components of the wave in the 50 to 500 kHz frequency range can transmit over larger distances, because of less attenuation. The lower-frequency signals in the 50-kHz range can be detected over relatively large distances on an uncoated surface. This means that some general source location can be performed using the lower-frequency components of the acoustic emission signal for large transducer separations, provided the signal attenuation (which increases when a vessel is coated and/or buried) does not reduce the surface wave to the extent that the true signal is lost in the background noise (Ref 9).

Source identification, however, requires the use of wide-band transducers operating at high frequencies and located as close as possible to the source of the emission. Only then is it possible to obtain some indication of the original waveform, and even then it will have been modified by its passage through the material to the surface so that care must be used in interpretation.

Other factors influencing the interpretation of results include:

- Defect type, size, shape, orientation, and location
- Chemical composition of the vessel material
- Vessel geometry and its associated pipework
- Epoxy-type coatings

Details on these factors can be found in Ref 9 and in the article "Acoustic Emission Inspection" in this Volume.

Proof Testing. Because the acoustic emission technique depends on a changing state of stress, especially around a discontinuity, the most convenient time for application to most pressure vessels is at the first proof test. With a sufficient number of search units, it is possible to monitor the entire vessel and locate the areas where discontinuities exist. Subsequent ultrasonic inspection can confirm the existence of very small acceptable discontinuities in the position indicated by the acoustic emission technique.

Test to Failure (Ref 9). In an attempt to improve the interpretation of acoustic emission data, tests have been conducted on operating vessels, static vessels, and vessels deliberately tested to failure. Data on wave propagation and failure mechanisms have been recorded and used to develop a reliable acoustic emission integrity evaluation technique. The following example illustrates the use of these tests.

Example 5: Test to Failure of a 10-Year-Old Pressure Vessel

(Ref 9). A vessel that had been in service for over 10 years and was operated at a normal pressure of 9.6 MPa (1400 psi) at 550 °C (1020 °F) was tested by acoustic emission and analyzed by subsequent fractographic examination. The defects causing its removal from service were extensive cracks in the nozzle reinforcement. These cracks ran circumferentially around the nozzle penetration, and those on the inside surface of the vessel were up to 25 mm (1 in.) deep. The test program was designed to pressurize the vessel to failure after many pressure cycles designed to accelerate the growth of flaws in the nozzle by cyclic fatigue. Numerous pressurizations were carried out at progressively increasing pressures, including a group of 995 cycles in the range of 7 to 24 MPa (1000 to 3500 psi).

The last four cycles were monitored with acoustic emission. The last three cycles were up to 58 MPa (8400 psi), and in the final pressurization, the failure of the vessel occurred at 62 MPa (9000 psi). There was considerable acoustic emission activity detected in the early stages of the test program, but this is thought to have resulted from movement of the vessel supported by observations using television monitors. After the pressure had exceeded 56 MPa (8100 psi), this acoustic emission activity diminished concurrently with the vessel becoming more settled on its supports. Two active source areas were localized at the bottom of adjoining nozzles. It was noted in this test that some of the location patterns were distorted due to some propagation paths being around nozzle holes in the vessel. During the final stages of the test, the acoustic emission event rate further diminished, which was partly due to the reduced pumping rate caused by the vessel expansion.

More acoustic emission activity was detected from the base of the central nozzle (No. 3, Fig. 15) than most of the other locations, and this primary initiation point for failure was later confirmed by independent fractography examination.

Fig. 15 Schematic of pressure vessel tested to failure and monitored by acoustic emission. Dimensions given in millimeters. Source: Ref 9

The failure was almost entirely brittle in character and appeared to be from localized exhaustion of ductility, with no apparent involvement of any significant preexisting defect. It appeared to propagate axially along the vessel from the initiation point and then to branch circumferentially between nozzle Nos. 2, 3, and 4, as shown in Fig. 15. Half of the vessel then lifted and separated, causing an axial fracture diametrically opposite the underside of these nozzles. This fracture acted as a hinge, which allowed this section to lift. The only evidence of ductile fracture was in a narrow shear lip adjacent to the external surface of the vessel.

The absence of a flaw at the point of initiation was somewhat surprising; however, the highly localized acoustic emission activity and subsequent failure may have resulted from a steep strain gradient adjacent to the reinforced and highly restrained nozzle penetration. The failure of the preexisting cracks to propagate confirms predictions of stress analysis that they were not located in highly stressed regions during simple pressurization. Their formation during service resulted from loadings imposed by external supports and pipework, rather than from internal pressure.

The conditions encountered in this test are clearly different from those that would exist in a nondestructive proof test. The vessel suffered extensive plastic deformation at pressure considerably higher than any conceivable proof test pressure. Also, the failure occurred by the local exhaustion of ductility in a highly strained region, rather than by the initiation of yielding in a highly stressed region. However, the ability of the equipment to identify localized acoustic emission sources was clearly demonstrated.

Inspection During Fabrication. During fabrication, acoustic monitoring can be used to detect cracking during or after the welding process. Stress-relief cracking can be identified as it occurs, although provision must be made for keeping the transducers at a low temperature. This is normally done by the use of waveguides, the extremities of which hold the transducers outside the stress-relieving furnace.

In-service inspection may consist of monitoring during periodic proof testing, during normal pressure cycles, or continuously during normal operation. When the vessel is pressurized to a level less than that to which it has been previously subjected (during, for example, the proof tests), little or no acoustic emission occurs. Therefore, on subsequent pressurizations a quiet vessel will be obtained unless a crack has extended in service because of corrosion or fatigue. On pressurizing after crack growth, the stress system at the enlarged crack will be changed from that in the proof test, and further emission will be obtained.

Flaw Location. In many cases, especially on large pressure vessels, it becomes necessary not only to detect acoustic emissions but also to locate the source of the signals. This can be accomplished by uniformly spacing multiple search units over the surface area of a pressure vessel and monitoring the time of arrival of the signals to the various search-unit locations. Because of the high velocity of sound and the relatively close spacing of search units on a steel vessel, time resolutions must be made in microseconds to locate the source to within a centimeter. In most cases, inspection requirements are such that data must be available in a short period of time. Therefore, most systems of this type utilize a computer for handling and displaying the data.

Introduction

THE RELIABILITY of a nondestructive inspection (NDI) procedure was defined in the article "Reliability of Flaw Detection by Nondestructive Inspection" in Volume 11 of the 8th Edition of *Metals Handbook* as a quantitative measure of the efficiency of that procedure in finding flaws of specific type and size. During the years since that article was published, many inspection reliability programs have been conducted, and various quantitative measurements have been cited to express the procedure capabilities. To establish the basis for NDI method reliability, it is necessary to review the history of NDI and its relation to reliability methods.

Historical Development of Quantitative Measurement Techniques

Nondestructive inspection methods are specified for material and/or component inspection requirements to maintain the necessary quality for the final service life of the material/component. In most industries, the inspection requirements are defined in a specification that describes the sensitivity level of the inspection method as well as the rejectable flaw size.

An example of a specification requirement is given in Table 1; the specification is based on longitudinal wave inspection using flat-bottom holes (FBH). It defines the ultrasonic inspection requirements for product over 13 mm (0.5 in.) thick. Table 1 indicates the defect detection/rejection limits for each quality class material. For example, quality class AA requires that single discontinuities be detected at a sensitivity level equivalent to a No. 3 (1.2 mm, or $\frac{3}{64}$ in., diam) FBH. In addition, multiple discontinuities* shall be detected at a sensitivity level equivalent to a No. 1 (0.4 mm, or $\frac{1}{64}$ in., diam) FBH.

Table 1 Typical NDI acceptance criteria

Five classes of ultrasonic quality are established for longitudinal wave inspection. These classes are defined for inspection involving flat-bottom reflectors in ultrasonic references.

Quality class	Single discontinuity ^(a) , FBH No.	Multiple discontinuities ^(a) , FBH No.	Maximum linear discontinuity, in.	Maximum loss of back reflection, %
AA	3	1 ^(b)	No. 1 response for 0.12	50
A1	3	2 ^(c)	No. 2 response for 1.00	50
A	5	3	No. 3 response for 1.00	50
B	8	5	No. 5 response for 1.00	50
C	As established by purchaser and vendor for specific part			

Source: Ref 1

(a) FBH numbers indicate diameter in multiples of 0.4 mm ($\frac{1}{64}$ in.) of FBH in ultrasonic reference.

(b) 11% of a No. 3 FBH is equivalent to a No. 1 FBH and can be used in place of the response from the No. 1 FBH.

(c) 44% of a No. 3 FBH is equivalent to a No. 2 FBH and can be used in place of the response from the No. 2 FBH.

Each specification also defines a procedure for demonstrating the capability to detect defects at the required sensitivity levels. In AMS 2630A, this defined procedure is a calibration technique used to set up the ultrasonic instrumentation. Ultrasonic standards have been designed to establish the performance of the inspection system. Procedures have been defined by the American Society for Testing and Materials for the manufacture of these ultrasonic reference blocks for longitudinal wave testing (Ref 2, 3). Finally, the specifications require specific training for the inspectors. For conformance with AMS 2630A, personnel must be certified to and function within the limits of their levels of certification as specified by the American Society for Nondestructive Testing (Ref 4). Further details of ultrasonic inspection procedures are described elsewhere in this Volume.

These specification requirements were designed to control the inspection processes and the quality of the inspection results. However, several catastrophic failures of major engineering systems (such as the F-111, space shuttle, nuclear reactors, and the Alaskan pipeline) and the development of advanced materials such as composites were major forces in the development and application of NDI technology (Ref 5). In concert with these events, a new design method using linear elastic fracture mechanics (LEFM) required inspection methodology for detecting defects in production and in service (for a description of LEFM, see *Mechanical Testing*, Volume 8 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*). Linear elastic fracture mechanics design assumes the presence of structural defects and then allows the designer to answer the following questions:

- What is the critical flaw size that will cause failure for a given component subject to service stress and temperature conditions?
- How long can a precracked structure be safely operated in service?
- How can a structure be designed to prevent catastrophic failure from preexisting cracks?
- What inspections must be performed to prevent catastrophic failure?

The ability to answer these questions forms the basis of *nondestructive evaluation* (NDE), which involves damage-tolerant design approaches and is centered on the philosophy of ensuring safe operation in the presence of flaws. The U.S. Air Force has used damage tolerance analysis, as shown in Fig. 1. The initial component in the as-manufactured condition is assumed to have a flaw of length a_0 . This flaw length is based on the manufacturing inspection capability or material flaw size distribution. The growth of the flaw is predicted for service usage and will reach a critical flaw size, a_f , after t_0 flight hours. The current Air Force philosophy requires an inspection at half the time required for the potential crack to grow to critical size. This inspection is assumed to detect and remove any flaw of size larger than a_{NDE} . The assumption creates the requirement to determine NDE probability of detection (POD) for this current design practice, as described in the articles that follow in this Section.

Fig. 1 Crack growth life curve for damage-tolerant design

The driving functions described above caused the NDE/NDI community to evaluate the inspection capabilities. The first evaluation in the aerospace industry was conducted by Lockheed in the 1970s and was called the "Have Cracks, Will Travel" program (Ref 6). This program was established to determine if airframe inspection would repeatedly detect cracks so that engineers could use LEFM philosophy for design. The study concluded that the overall reliability of NDI performed by the Air Force and evaluated in the program falls below that which has been previously assumed by established guidelines (Ref 6). The most significant result of the program was that the 90/95 reliability criteria could not be attained for any flaw size with typical inspection techniques applied by the average technician. Many advancements have been made in NDE/NDI technology to improve the inspection capability since this study. These technologies are described throughout this Volume.

- * Multiple discontinuities are defined in AMS 2630A as two or more indications above the level established for the class that occur within 16 cm³ (1.0 in.³) of the inspected surface.

NDE Reliability

The following article in this Section--"Fracture Control Philosophy"--describes the U.S. Air Force philosophy for current design practices. Damage-tolerant design requires knowledge of the reliability of the inspection technique used to detect flaws or damage. In the initial stages of using this design approach, a one-number characterization of NDE capability was in use. The one-number characterization was the minimum crack (flaw) length for which there is a fixed degree of confidence that at least a fixed probability of cracks will be detected. Typically, the minimum crack length was chosen such that, at the 95% confidence level (CL), at least 90% of all cracks greater than this length will be detected. The number is referred to as the 90/95 (POD/CL) crack length.

Probability of detection functions for describing the reliability of an NDE technique have been the subject of many studies. The ideal inspection system POD function is shown schematically in Fig. 2. All flaws larger than a_{NDE} would be detected all of the time, while all flaws smaller than a_{NDE} would not. Obviously, no ideal system exists, and the POD functions used produce a continuous curve. Figure 3 shows a POD curve for an automated eddy current inspection of titanium bolt holes. Two confidence level POD curves are shown, 50 and 95%. Berens and Hovey completed a study that compared POD analysis techniques to determine the optimum calculation method (Ref 7). Additional information concerning the analysis of NDE data for the determination of reliability is available in the article "NDE Reliability Data Analysis" in this Section.

Fig. 2 Schematic of probability of detection curves

Fig. 3 POD curve for the automated eddy current inspection of titanium bolt holes

The accuracy of the POD function is dependent on the demonstration program design. The data acquired during the demonstration program testing can influence the resulting prediction of reliability. For example, consider the cases presented in Fig. 4, which graphically presents the specimen/crack depth histogram for two case studies. If the design requirement is such that a_{NDE} (that is, 90/95 crack depth) must be 250 μm (10 mils) or less, only the specimens in case study No. 2 could demonstrate this capability. That is, to demonstrate 90/95 crack size, the specimens fabricated for the demonstration program must have cracks less than a_{NDE} and some larger. If it is assumed that all the flaws were detected in both cases, the 90/95 crack sizes predicted are as follows:

Case study	90/95 crack size	
	μm	mils
1	417	16.40

Fig. 4 Specimen crack depth distribution for two case studies. (a) Case study No. 1. (b) Case study No. 2

This case study, which demonstrates the criticality of planning the reliability demonstration program, showed only the importance of specimen flaw size to the final outcome of the reliability study.

In the following articles in this Section, fracture control philosophy is discussed, reliability demonstrations that have been completed are reviewed, and the analysis of NDE data is examined. The final article in this Section, "Models for Predicting NDE Reliability," provides information on advanced modeling studies for predicting reliability for the inspection of a particular component. The objective of this Section is to provide the necessary information and resources to conduct an effective NDE reliability program.

Fracture Control Philosophy

William D. Cowie, United States Air Force, Aeronautical System Division, Propulsion Directorate

Introduction

FRACTURE CONTROL PHILOSOPHIES are being used in the design, development, and life management of United States Air Force (USAF) turbine engine and airframe components. This article describes the fracture control program for turbine engine components. The section "Applications (Case Studies)" of the article "Applications of NDE Reliability to Systems" in this Volume provides an overview of fracture control programs for both airframe and turbine engine components.

The establishment of a fracture control philosophy and the implementation of a fracture control program have been integral components of the USAF turbine engine development process since 1978. They have been applied to new engine programs as part of the USAF Engine Structural Integrity Program (ENSIP) described in military standard MIL-STD-1783 (issued formally in 1984). This military standard was reviewed and approved by the Aerospace Industries Association of America in 1982.

Fracture control philosophy has also been applied to existing inventory USAF engines through structural durability and damage tolerance assessments. In all, fracture control programs have been applied or are being applied to the F-100, TF-34, F100-PW-220, F100-PW-229, F110-GE-100, F110-GE-129, F101-GE-102, F109-GA-100, F-119, F120, and T406 engines and have resulted in the implementation of enhanced nondestructive evaluation (NDE) methods (for example, eddy current inspection) at manufacturing and at field/depot. These inspections have been successful in detecting early cracking and in accelerating corrective actions. Several developmental efforts in the last 5 years have identified fluorescent penetrant inspection process improvements that must be implemented within industry and Air Force depots to improve flaw detection reliability. The need to quantify detection reliability for imbedded defects is also identified.

The engine development process has been evolutionary in terms of the application of upgraded requirements. The new process of fracture control, sometimes referred to as damage tolerance, is contained in ENSIP, and it involves material selection as well as design and life management. Recent experience clearly demonstrates that the damage tolerance requirement is cost effective when assessed on a life cycle basis.

Fracture Control Philosophy

William D. Cowie, United States Air Force, Aeronautical System Division, Propulsion Directorate

Overview of ENSIP

In the past 16 years, a large number of structural problems have occurred in USAF gas turbine engines. Many of these were safety problems that resulted in loss of aircraft, and an even greater number affected durability, causing a high level of maintenance and modification costs. All of these problems have adversely affected fleet readiness. The Engine Structural Integrity Program was intended to reduce these problems substantially and was developed based on the following specific lessons:

- It is unrealistic (and can be dangerous) to assume defect-free structure in safety-of-flight components
- Critical parts (and part details) and potential failure modes must be identified early and appropriate control measures implemented
- Internal thermal and vibratory environments must be identified early in the engine development
- Predicted analytical stresses must be verified by test for complex components
- Materials and processes must be adequately characterized (particularly, the fracture properties)
- Design stress spectra, component test spectra, and full-scale engine test spectra must be based on the anticipated service usage of the engine, that is, accelerated mission-related testing
- Potential engine/airframe structural interactions must be defined and accounted for
- Management procedures (such as individual engine tracking procedures and realistic inspection and maintenance requirements) must be defined and enforced

The Engine Structural Integrity Program was established by the Air Force to provide an organized and disciplined approach to the structural design, analysis, development, production, and life management of gas turbine engines, with the goal of ensuring engine structural safety, increased service readiness, and reduced life cycle costs. The five major tasks associated with ENSIP are the development of design information; design analysis and component and material characterization; component and core engine testing; ground and flight engine testing; and production quality control and engine life management. Each major task is subdivided into a number of subtasks (Table 1) that guide the development process.

Table 1 Tasks of the engine structural integrity program

Task I: Design information
Development plans
ENSIP master
Durability and damage control
Material and process characterization
Corrosion prevention and control
Inspection and diagnostics
Operational requirements
Design service life and usage requirements
Design criteria
Task II: Design analysis and material characterization and development tests
Design duty cycle
Material characterization
Design development tests
Structural/thermal analysis
Installed engine inspectability
Manufacturing and quality control

Task III: Component and core engine tests

Component tests

Strength
Vibration
Damage tolerance
Durability

Core engine tests

Thermal survey
Vibration strain and flutter boundary survey

Task IV: Ground and flight engine tests

Ground engine tests

Strength
Damage tolerance
Accelerated mission test
Thermal survey
Vibration strain and flutter boundary survey

Flight engine tests

Fan strain survey
Thermal survey
Installed vibration
Deterioration

Task V: Engine life management

Updated analyses
Structural maintenance plan
Operational usage survey
Individual engine tracking
Durability and damage tolerance control actions (production)

The Engine Structural Maintenance Plan represents the output of the ENSIP program. This plan identifies and defines individual part life limits, the necessary inspection periods for each fracture-critical part, and the inspection procedure. The basic components of the Engine Structural Maintenance Plan are as follows:

- Structural safety is obtained in ENSIP by requiring a structure with a damage tolerance that is capable of accommodating flaws induced either in manufacture or service
- Durability design requirements stipulate that the economic life of the engine must exceed the specified design service life of the aircraft when flown to the design usage spectra
- Maintainability criteria require that old parts fit and function with new parts, that repair life be defined,

- and that inspectability and structural diagnostics be designed into the engine and its components
- A materials and process characterization plan controls materials development through key engine development points
- Environmental definition requirements specify the thermal, dynamic, and steady-state stress; the stress spectra; and the component sensitivities
- A comprehensive ground test policy is utilized to ensure compliance with safety, durability, and maintainability requirements
- A usage and tracking policy is used to form the basis of an engine life management program

Fracture Control Philosophy

William D. Cowie, United States Air Force, Aeronautical System Division, Propulsion Directorate

ENSIP and Fracture Control Philosophy Policy

Damage tolerance is defined as the ability of the engine to resist failure due to the presence of flaws, cracks, or other damage for a specified period of usage. The damage tolerance or fracture control philosophy used in ENSIP is shown in Fig. 4. Components are designed for crack growth so that the safety limit exceeds two times the required inspection interval. The safety limit or residual life is the time for assumed initial flaws to grow and cause failure. Because the requirement is to inspect at one-half the safety limit, the design goal for the safety limit is two times the required design life (that is, no inspections). The minimum design requirement for the safety limit is two times the planned depot visit interval. An important aspect of the damage tolerance requirement is that it applies only to fracture-critical components.

Fig. 4 Damage tolerance approach to life management of cyclic-limited engine components. The safety limit or residual life is the time for the initial flaw to grow and cause failure. The size of the initial flaw, a_i , is based on the inspection method or material defect distribution (for imbedded defects).

Fracture-critical components are defined as those components whose failure will result in probable loss of the aircraft due to noncontainment or, for single-engine aircraft, power loss that presents sustained flight because of direct part failure or by causing other progressive part failures. Damage tolerance requirements are applied only to fracture-critical components (that is, components that must maintain their integrity during flight) and not, in general, to durability-critical components (that is, components that affect maintenance schedules). As expected, component classification is affected by aircraft engine configuration (single engine or multiengine). Component classification is established early and is identified in the contract.

Initial Flaw Size. Initial flaws are assumed to exist in fracture-critical components. Experience has shown that premature cracking (that is, crack initiation prior to the LCF limit) occurs at high-stress areas and where components initially contained both material- and manufacturing-related quality variations (voids, inclusions, machining marks, scratches, sharp cracks, and so on). The fracture control or damage tolerance requirement assumes a sharp crack as the initial flaw when characterizing these abnormal initial conditions. The assumed initial imbedded flaw sizes are based on the intrinsic material defect distribution or the NDE methods to be used during manufacture. The assumed surface flaw size also depends on the NDE capability. An inspection reliability of 90% probability of detection (POD) at the lower-bound 95% confidence level (CL) is required for the assumed initial flaw sizes.

The assumed initial flaw size to account for intrinsic material defect distribution should encompass 99.99% of the defect population if a scatter factor of two is used to establish the inspection interval, or 99.9% if a scatter factor of one is used. If embedded defects cannot be inspected in service, the 99.99 percentile (or the 99.9 percentile) is used to satisfy the design life requirement.

An initial flaw size not less than 0.75 mm (0.030 in.) in length (for surface flaws) or 0.4×0.4 mm (0.015×0.015 in.) in size (corner cracks) for nonconcentrated stress areas (bores, webs, and so on) is required. Initial flaw sizes for other surface locations (holes, fillets, scallops, and so on) will be consistent with the demonstrated capability (90% POD/95% CL) of the inspection systems proposed for use. It is recommended that the initial design and sizing of components be based on 0.75 mm (0.030 in.) long surface flaws or 0.4×0.4 mm (0.015×0.015 in.) corner cracks at all locations. This design recommendation is based on the initial flaw size that can be detected with fluorescent penetrant inspection. This includes fully automated fluorescent penetrant inspection systems that are being developed to meet the 0.75 mm (0.030 in.) and 0.4×0.4 mm (0.015×0.015 in.) inspection criteria.

These flaw sizes are intended to represent the maximum size of the damage that can be present in a critical location after manufacture and/or inspection. The specification of these flaw sizes is based on the demonstrated flaw detection capability of the nondestructive inspection (NDI) method. During design of the components, the assumed initial flaw size that is appropriate for various NDI methods is:

- 0.75 mm (0.030 in.) surface length where the NDI method is fluorescent penetrant inspection
- 0.25 mm (0.010 in.) surface length where the NDI method is eddy current or ultrasonic inspection
- 1.3 mm² (0.002 in.²) area for imbedded defects utilizing ultrasonic inspection
- 5 mm (0.200 in.) surface length and imbedded sphere = $0.2 \times \text{thickness}$ for weldments
- When initial flaw sizes are based on material defect distribution, selected size shall encompass 99.99% of the distribution
- Demonstration that assumed flaw sizes can be reliably detected with a 90% POD and a 95% CL

The capabilities of the NDI method must be demonstrated by the contractor. The design of NDE reliability experiments is discussed in the article "NDE Reliability Data Analysis" in this Volume.

Residual strength is defined as the load-carrying capability of a component at any time during the service exposure period, considering the presence of damage and accounting for the growth of damage as a function of exposure time. The requirement is to provide limit load residual strength capability throughout the service life of the component. In other words, the minimum residual strength for each component (and location) must be equal to the maximum stress that occurs within the applicable stress spectra based on the design duty cycle. Normal or expected overspeed due to control system tolerance and engine deterioration is included in the residual strength requirement, but fail-safe conditions, such as burst margin, are excluded. The residual strength requirement is illustrated in Fig. 5.

Fig. 5 Diagram of the residual strength requirement

specification.

Inspection Intervals. It is highly desirable to have no damage tolerance inspections required during the design lifetime of the engine. This in-service noninspectable classification requires that components be designed such that the residual life or safety limit be twice the design life. Designing components as in-service noninspectable is a requirement for those components or locations that cannot be inspected during the depot maintenance cycle.

However, the weight penalty incurred to achieve a safety limit/residual life/damage growth interval twice the design life may be prohibitive on some components/locations. Therefore, in-service inspections will be allowed on some components subject to justification. The basis for the justification is characterization of the costs as a function of the requirements as established by trade studies. Cost is usually expressed in terms of weight or life cycle cost, and the requirement in terms of safety limit/residual life/damage growth interval.

The depot or base-level inspection interval for damage tolerance considerations should be compatible with the overall engine maintenance plan. Once again, it is highly desirable that the inspection interval be equal to the design service life of the parts in the hot gas path (that is, the hot-part design service life, which is equal to one-half the design lifetime of the engine) because this is the expected minimum depot or maintenance interval for the engine or module. It is required that the minimum damage tolerance inspection interval be contained in the contract

Flaw Growth. It is required that the assumed initial flaw sizes will not grow to critical size and cause failure of a component due to the application of the required residual strength load in two times the inspection interval. The flaw growth interval is set equal to two times the inspection interval to provide a margin for a variability that exists in the total process (that is, inspection reliability, material properties, usage, stress predictions, and so on). Factors other than two should be used when individual assessments of the variables that affect crack growth can be made (for example, to account for observed scatter in crack growth during testing).

It is important that the effects of vibratory stress on unstable crack growth be accounted for in establishing the safety limit. Experience shows that the threshold crack size can be significantly less than the critical crack size associated with the material fracture toughness, depending on the material, the major stress cycle, and the vibration stress. As shown in Fig. 6, the conventional Goodman diagram may not disclose the true sensitivity of initial defects to vibratory stresses. The threshold crack size must be established at each individual sustained-power condition (idle, cruise, intermediate) using the appropriate values of steady stress and vibratory stress. The smallest threshold crack size will be used as a limiting value in calculating the safety limit if it is less than the critical crack size associated with the material fracture toughness.

Fig. 6 Interaction of vibratory stress and initial flaws. (a) Large vibratory stress required to initiate crack. (b) Low vibratory stress will propagate cracks. The crack growth threshold, A_t , represents the threshold of vibratory motion that will cause the growth of a given crack size.

Fracture Control Philosophy

William D. Cowie, United States Air Force, Aeronautical System Division, Propulsion Directorate

Fracture Control Verification

Verification that the fracture control policy is met is accomplished by the development and implementation of a Damage Tolerance Control Plan, by analysis and test, and by the implementation of reliable inspection methods during manufacture and field/depot maintenance.

A **Damage Tolerance Control Plan** is prepared that identifies and schedules each of the tasks and interfaces in the functional areas of design, materials selection, tests, manufacturing control, and inspection. Specific tasks that are addressed in the Damage Tolerance Control Plan are:

- Trade studies for design concepts/material/weight/performance/cost
- Analysis
- Development and qualification tests
- Fracture-critical parts list
- Zoning of drawings
- Basic materials fracture data
- Material properties controls
- Traceability
- NDI requirements

Most of the tasks to be contained in the Damage Tolerance Control Plan have been accomplished by engine manufacturers in past development and production programs. However, the damage tolerance requirement now established by the Air Force imposes the need for new tasks as well as tighter controls and more involvement among the functional areas. Experience indicates that the development and implementation of a Damage Tolerance Control Plan are difficult, but experience also shows very strongly that the development of a plan results in an improved understanding of what must be done. The importance of having a plan rests on the involvement of multiple functional areas and the criticality of having assigned responsibilities for each task.

A particularly important part of the Damage Tolerance Control Plan is the requirement for early trade studies for design concepts/materials/weight/performance/cost. These trade studies are critical to defining cost versus requirement (for example, weight impact versus inspection interval).

Analysis and Test Correlation Requirement. The procedure for the analysis of damage tolerance includes the development of stress spectra (Fig. 7) and the analysis and testing of residual life (Fig. 8). Particular emphasis is placed on establishing a correlation between analytical predictions and test measurements for the growth of cracks in critical areas. Refined analysis models that predict the stress state at and away from the surface, as well as multiple cyclic tests of coupons, subcomponents, and full-scale components in the presence of initial damage, are required. As with the overall ENSIP development philosophy, damage tolerance analysis and tests are conducted early with minimum impact. Test requirements include:

- Specimen tests to define basic material fracture data, such as the plane-strain fracture toughness (K_{Ic}), the plane-stress fracture toughness (K_{Ic}), the threshold stress intensity for stress-corrosion cracking (K_{Isc}), and the crack growth curve, which defines the crack growth rate da/dN (where a is the crack length and N is the number of cycles)
- Subcomponent tests to evaluate crack growth at typical critical features, such as bolt holes and fillet radii
- Spin pit test of full-scale components, such as disks, spacers, or rotors
- Engine testing of preflawed components

Fig. 7 Development of stress spectra

Fig. 8 Residual life analysis and test procedure

A typical test configuration for a cyclic spin test is shown in Fig. 9, and typical empirical data are shown in Fig. 10, 11, 12. Verification requirements may also include engine test with components that are preflawed or cracked in critical locations to determine the effects of the real environment (temperature and gradient, vibration, and so on). Such tests must be closely controlled and monitored using the inspection requirements planned for service engines to ensure safety of the test engine.

Fig. 11 Actual and predicted flaw growth for an engine test on a second-stage high-pressure turbine disk forward cooling air hole

Fig. 12 Methodology correlation (specimens and components)

Nondestructive evaluation requirements are implemented on fracture-critical parts during manufacture and during field/depot inspection to ensure safety. Specific inspection requirements are derived through design analysis trade-offs among initial flaw size assumption, stress level, and material properties for a given usage (stress environment spectrum). As discussed in the section "Initial Flaw Size" in this article, a flaw size assumption (for surface flaws) of less than 0.75 mm (0.030 in.) requires implementation of enhanced NDE (that is, eddy current inspection). The ability of eddy current inspection to reliably detect surface flaws having depths of 0.13 mm (0.005 in.) has been demonstrated in several applications. Primary emphasis on the use of eddy current inspection is for stress concentration areas in which a small flaw size assumption is required to achieve the necessary residual life without excessive weight penalty. Typical probability of detection data for eddy current inspection in Fig. 13.

Fig. 13 POD curves with eddy current inspection. All curves are for lower 95% confidence limit.

In general, fluorescent penetrant inspection is specified for areas in which the detection of a flaw with a surface length of 0.75 mm (0.030 in.) or larger is required to achieve the specified residual life. However, the ability of current fluorescent penetrant inspection processes to reliably detect 0.75 mm (0.030 in.) flaws is not clear. Therefore, in some cases, eddy current inspection may be specified for large areas if susceptibility data (that is, probabilistic data on the capability of fluorescent penetrant inspection) indicate the need. Data generated on numerous demonstration programs clearly indicate that the fluorescent penetrant inspection process can be significantly improved through upgraded training, equipment, and procedures (proper cleaning, including etch, hydrophilic emulsifier, and wet developer). These demonstration programs have been conducted on several engine development programs (F100, F101, F110, F110-GE-129, F100-PW-229) and laboratory technology programs (Air Force Wright Research and Development Center). Some typical detection improvements that have been demonstrated for upgraded fluorescent penetrant inspection processes are shown in Fig. 14. The critical need is to implement the best fluorescent penetrant inspection process within industry and within the Air Force logistics centers because this method will likely remain the most widely used for inspecting large areas for cracklike damage.

Fig. 14 Probability of detection with fluorescent penetrant inspection. LCL, lower confidence limit

Another critical NDE need is to quantify the POD of ultrasonics to detect imbedded defects in bulk volumes and to develop inspection methods for finished shapes. Very limited data indicate that reliable detection limits may be as large as 1.3 mm^2 (0.002 in.^2) (approximately equal to a planar disk of 1.2 mm, or $\frac{3}{64}$ in., diameter). The goal is to develop and implement ultrasonic inspection methods such that a residual life equal to two times the required life or the inspection interval can be achieved, assuming the largest undetectable flaw size without excessive impact on weight.

Retirement-for-Cause (RFC). Traditionally, components whose dominant failure mode is low-cycle fatigue have been designed to a crack initiation criterion. With this approach, only 1 component in a population of 1000 would have actually initiated a crack, and the remaining 999 components would be discarded with substantial undefined useful life to crack initiation remaining. Figure 15 shows that the difference between the number of cycles to reach the design-allowable curve and the population average curve for an average component would have consumed only 10% or less of its potential useful life-to-crack initiation. Under the initiation criterion, there is no way to utilize this potential life without accepting a higher probability of failure of the remaining components.

Fig. 15 Stress versus loading cycles to crack initiation for Inconel 718. Temperature is 540 °C (1000 °F), and the ratio of alternating stress to mean stress (A ratio) = 1.

Under the RFC concept, this additional useful life can be utilized by adopting a rejection criterion that uses each component in a population until it specifically initiates a crack, rather than rejecting the entire population on the behavior of the statistical minimum. The development of fracture mechanics concepts over the last several years has permitted the degree of predictability for crack propagation rates necessary to implement such an approach on a safe basis.

The RFC concept would apply the fracture control philosophy (Fig. 4) to life management. In using RFC as an operating system, all components would be inspected first at the end of a safety limit period divided by an appropriate safety margin, and only those components containing detectable cracks equal to or greater than a_i would be retired or repaired. All others would be returned for additional service (with the assumption that if a flaw existed, it would be smaller than a_i for another inspection interval). In this way, the crack propagation residual life is continually reset to a safe value. By following this approach, components are rejected only for cause (cracks), and each component is allowed to operate for its own specific crack initiation life. It should be noted that if a crack is missed at the first inspection interval, another chance should exist to find a larger crack.

It is clear that not all fatigue-limited components can be handled in this way and that each component must be evaluated individually to determine the technical feasibility of RFC. Low-cycle fatigue is a real physical phenomenon that is not directly associated with the presence of defects. Any criterion, initiation or otherwise, that allows components to run beyond a design-allowable life (-3σ , for example) or beyond the average life will inherently result in a significant increase in the probability of a large number of cracks and possible failures. Such an increase in risk may be acceptable, but must be understood and evaluated. Any inspection process has associated with it a finite probability of detection and therefore a finite probability of missing real cracks (not just defects assumed to be there and assumed to be in the form of sharp cracks). Missing real cracks and presuming that crack growth knowledge is sufficient to detect cracks at the next inspection has significantly more risk associated with it than concern over possible defects.

The economic feasibility of RFC must also be evaluated. The inspection interval must be such that it does not place undue constraints on the operation of the component or that the cost of the necessary tear-down and inspection does not negate the advantage of the life extension. It seems unlikely that RFC can be applied to components limited by high-cycle fatigue considerations, but for many high-cost components limited by low-cycle fatigue, such as engine disks, this approach does offer significant economic advantages.

It is also clear that in applying RFC, nondestructive evaluation becomes a critical factor. The crack length determines the residual life of the component, and its detection is limited by the resolution and reliability of the inspection system employed. In many cases, the decision as to whether or not RFC can be applied to a component will be predicated upon the ability of available NDE approaches to detect the initial flaw, a_i , with sufficient sensitivity and reliability. Because RFC procedure is based on fracture control concepts, the NDE techniques can be selected, refined, and focused on a particular local area, rather than attempting to critically inspect large areas.

Applications of NDE Reliability to Systems

Ward D. Rummel, Martin Marietta Astronautics Group; Grover L. Hardy and Thomas D. Cooper, Wright Research & Development Center, Wright-Patterson Air Force Base

Introduction

THE SUCCESS of a reliable NDE application depends greatly on the expertise and thoroughness of the NDE engineering that is performed. This involves comprehensive analyses to define the relationships between the NDE measurements to be made and the impact on the system functions being assessed and on the capability to implement the NDE measurements to discriminate to the expected level of acceptance applied. Most failures in NDE systems applications and in the automation of an NDE system can be attributed to failures in NDE engineering and to unrealistic NDE performance expectations. All modern engineering is based on comprehensive applications of principles that can be implemented by qualitative measurements and predictive modeling and on comprehensive procedural applications of principles based on prior art and systems test data. Modern engineering methods are equally applicable to the use of NDE on a material, component, structure, or system. The principles and data available are, however, not as well defined, generally recognized, or understood as those of other engineering disciplines.

Applications of NDE Reliability to Systems

Ward D. Rummel, Martin Marietta Astronautics Group; Grover L. Hardy and Thomas D. Cooper, Wright Research & Development Center, Wright-Patterson Air Force Base

General Considerations

Prior Art. Particular concern must be given to NDE assessment and analyses based on prior art. Although NDE methods and principles have been applied since the beginning of time and have been applied specifically to quantitative materials evaluation during the last decade, the perceived performance level is often considerably different from the actual performance level. Differences can be attributed to the primitive level of understanding of materials, engineering, and NDE engineering sciences and principles; excessive optimism in effecting early application of an NDE procedure; economic and social pressure to solve problems with troublesome engineering systems; and the attitudes and practices of our legal system.

Progressive developments in the evaluation of NDE reliability have established a new dimension for the assessment of NDE performance. Applications of prior NDE art must be judiciously examined to determine suitability for new applications. Quantification of the performance level, calibration (or process control) methods, and acceptance criteria are

particularly important in extrapolating the applicability of prior NDE data to a new NDE engineering problem. Conversely, the lessons learned in applications of prior art can be very useful in design and calibration and process control procedures, in establishing the characteristics and performance of materials and equipment used, in anticipating the problems and controls necessary to effect application in a production environment, and in assessing human factors relevant to the application.

Incorporation and integration of the qualitative factors and considerations in the application of prior art are essential for making the transition from laboratory test data to production line use. However, careful analysis and criteria must be applied to quantitative data from application of prior art. Quantitative assessment of ongoing NDE process applications has shown that performance levels may vary considerably in NDE applications to established specification/process requirements. Performance variations are rarely integrated into overall system reliability estimates and management is rarely accurate in recognizing and identifying superior performance by human operators. Quantitative data must be supported by actual NDE system measurements and accurate descriptions of NDE materials, equipment, procedures, and human operator qualifications to be seriously considered in NDE system design or qualification by similarity. It must be emphasized that quantitative data are not necessary for the multitude of NDE applications used to add confidence to routine process control and other applications in which the NDE procedure does not constitute final acceptance of performance characteristics. Quantitative data are required when the NDE measurement/acceptance is integral to design acceptance and/or performance acceptance.

NDE Response. The response from an NDE system or process may take the form of a signal output (or outputs) or a direct or indirect image. Acceptable conditions can be differentiated from unacceptable conditions by threshold discrimination from the electronic output or by pattern recognition and threshold discrimination by image analyses. Discrimination can be automated or performed by a human operator. Discrimination of threshold electronic signals can be automated or gated to alert the human operator. The consistency and reliability of electronic signal discrimination can often be improved by automating the discrimination process. Superior consistency and reliability of pattern recognition and discrimination level for images are usually achieved by the human operator. The feasibility of application of NDE to a system is dependent on the establishment and characterization of a relationship between the response from an NDE output and a desired engineering system performance parameter.

A direct or indirect relationship between an NDE response and a system performance characteristic may be functional under laboratory conditions, but may be impractical in applications under production or service conditions. Factors such as calibration, acceptance criteria, component accessibility, surface condition, inspection material compatibility, and inspection environment must be assessed to determine that a positive relationship between NDE response and system performance can be maintained.

NDE System Management and Schedule. The implementation of a reliable NDE procedure is dependent on allowing time to collect data, perform the critical analyses, apply required resources, and develop operator (personnel) skills. Many critical NDE procedures have been implemented as a result of unanticipated engineering system failures. The economic and social pressures resulting from an engineering system failure must be judiciously balanced against the required time and resources necessary to perform disciplined and thorough NDE engineering analyses, procedure development, and procedure validations. After the required procedures have been implemented, NDE system/process control must be maintained to ensure a consistent level of discrimination. Shortcuts in NDE engineering, NDE procedure development, and NDE system/process control increase risks in system performance, may not reduce the risk of engineering system failure, and may contribute to a false confidence level in system performance.

Applications of NDE Reliability to Systems

Ward D. Rummel, Martin Marietta Astronautics Group; Grover L. Hardy and Thomas D. Cooper, Wright Research & Development Center, Wright-Patterson Air Force Base

NDE Engineering

The difference between NDE engineering and the classical engineering disciplines result from the variety of problems and the indirect nature of NDE measurements on engineering system performance. The functional performance of most NDE methods can be measured, controlling parameters can be documented, and performance output can be modeled; however, the interaction of the NDE method with the test object necessitates the generation of new response parameters and

characteristics for many new applications. In addition, variations in material properties, geometry, surface condition, access, or environmental conditions may modify the NDE responses. Therefore, NDE engineering is an essential element of critical engineering system design, qualification, acceptance, and life cycle management. A critical design is not complete until the NDE engineering has been performed and NDE system/process performance validated to functional design requirements and acceptance criteria levels.

Procedure Selection/Development. Trade studies to identify and select candidate NDE procedures are needed for establishing the most economical and reliable procedure that meets acceptance requirements. The process may be satisfied by the assessment of prior art and applications to similar problems or may require research and development of totally new procedures. For demanding applications, a combination of complementary NDE procedures may be required to meet the acceptance criteria objectives. One or more methods can be further characterized and assessed to ensure that the performance objectives, NDE performance margins, NDE costs, engineering system performance risks, and the risks of NDE system/process false alarms can be balanced in overall engineering system management.

System/Process Performance Characteristics. Although care, discipline, and control measures are applied to ensure a consistent output from an NDE system or process, the output will vary within the established control parameters and as a result of slight variations in engineering hardware materials properties, geometry, surface condition, and so on. If repetitive applications are made, a probability density distribution of signal/image output will be generated. This distribution is similar to that obtained by repetitive measurements of a dimension such as a hole diameter or the length of a bolt.

Nondestructive measurements are usually indirect, and positive signals may be generated from nonrelevant sources, such as surface roughness, grain structure, and geometry variations. Such signals constitute the application noise inherent in a specific NDE process or procedure. Discrimination of NDE signal/image outputs must be derived from those signal levels/amplitudes that exceed the level of the application noise (Fig. 1). Analysis of signal and signal plus noise are common in electronic devices, optics, and other discrimination processes. Similarly, the signal-to-noise margin (ratio) is a primary factor in establishing the level of discrimination of an NDE procedure. Signal/noise reduction procedures can be used to enhance the overall performance of an NDE procedure. However, it is important to recognize that the dominant noise source in an NDE process is not electronic noise that may be reduced by filtering, multiple sampling, and averaging techniques, but is instead the noise due to nonrelevant signals generated in applying the NDE procedure to a specific hardware element.

Fig. 1 Signal/noise density distribution for a large flaw (a), a medium flaw (b), and a small flaw (c)

Conditional Probability in NDE Discrimination. Nondestructive evaluation involves the measurement of complex parameters with inherent variations in both the measurement process and the test object. The output from such a measurement/decision process can be analyzed as a problem in conditional probability. When an NDE assessment is performed for the purpose of crack detection, the outcome is not a simple accept/reject (binary) process, as is frequently envisioned. It is actually the product of conditional acceptance due to the interdependence of the measurement and decision responses. Figure 2 shows the four possible outcomes that result from the application of NDE procedure for crack detection. As shown in Fig. 2, the possible outcomes from an inspection process are:

- **True positive (TP):** A crack exists and is detected, where $M(A,a)$ is the total number of true positives and $P(A,a)$ is the probability of a true positive

- *False positive* (FP): No crack exists but one is identified, where $M(A,n)$ is the total number of false positives and $P(A,n)$ is the probability of a false positive
- *False negative* (FN): A crack exists but is not detected, where $M(N,a)$ is the total number of false negatives and $P(N,a)$ is the probability of a false negative
- *True negative* (TN): No crack exists and none is detected, where $M(N,n)$ is the total number of true negatives and $P(N,n)$ is the probability of a true negative

The interdependence of these matrix quantities can be expressed as:

$M(A,a) + M(N,a) =$ (TP) and (FN) outcomes giving the total opportunities for positive calls (Total number of defects)

and

$M(A,n) + M(N,n) =$ Total opportunities for false alarms from the possible (FP) and (TN) outcomes

		Inspection stimuli	
		Positive, a	Negative, n
Inspection response	Positive, A	True positive (flaw detected) $M(A,a)$ $P(A,a)$ (no error)	False positive (false alarm) $M(A,n)$ $P(A,n)$ (type II error)
	Negative, N	False negative (undetected flaw) $M(N,a)$ $P(N,a)$ (type I error)	True negative (no flaw) $M(N,n)$ $P(N,n)$ (no error)

Fig. 2 Matrix of four possible outcomes from an NDE procedure for flaw detection

Because of the interdependent relationship, only two independent probabilities need be considered to quantify the inspection/decision task. The probability of detection (POD) or probability for a true positive $P(A,a)$ can be expressed as:

$$P(A,a) = \frac{M(A,a)}{M(A,a) + M(N,a)} \text{ or } \frac{\text{Total true positive calls}}{\text{Total number of defects}}$$

Similarly, the probability of false alarms (POFA) or the probability for a false positive $P(A,n)$ can be expressed as:

$$P(A,n) = \frac{M(A,n)}{M(A,n) + M(N,n)} \text{ or } \frac{\text{Total false alarms}}{\text{Opportunities for false alarms}}$$

Signal/Noise Relationships. The desired results of the application of NDE procedure are crack detection (signal present) or crack nondetection (signal absent). The basis for detection is that of sensing a signal response and determining that the signal response is above a predetermined threshold. Both sensing and interpretation are dependent on the signal (plus noise) and the noise (application background or response to nonrelevant parameters) that are subjected to the discrimination media (programmed machine discriminator or human operator).

If an NDE procedure is repetitively applied to a single flaw of a given size (in a part with a fixed geometry, surface condition, and so on), the output responses can be used to plot probability density distributions of both flaw signal and application noise responses. Under ideal conditions, such as the response from a large flaw, the signal and noise distributions will be well separated, as shown in Fig. 1(a).

The discrimination of flaw responses from application noise responses is a simple process; POD will be high, and the POFA will be low. In practical engineering applications, the flaw size is not fixed (and is rarely large), and the discrimination process is more complex. Indeed, the discrimination process is applied to a continuous range of flaw sizes, where the capability for discrimination is dependent on the inherent performance characteristic of the NDE procedure and on the separation of the signal (plus noise) from the noise response of the process.

If the NDE procedure is applied to a single flaw of intermediate size (in a part with the same fixed surface finish, geometry, and so on), the output responses can be used to generate probability density distributions for signal and noise, as shown in Fig. 1(b). For this flaw size, the distributions overlap (in part), and the capability for discrimination is dependent on the response from a single set of output signals within these distributions. If the single set has output signals that are well separated (that is, signals at the outer extremes of the distributions), the output response will be interpreted as acceptable (no flaw condition) for those cases where the threshold response acceptance level is located between the signal and noise signals. If the single set of outputs lies at the inner extremes of the distributions, the output response may be interpreted as acceptable (no flaw or undetected flaw condition) or may be interpreted as unacceptable (false alarm condition) for the same threshold response acceptance level. For this condition, the POD will be lower and the POFA will be higher than for the case of discrimination with positive signal/noise separation margins. If the process is repeated for a small flaw (under the same operating conditions), the signal and noise response distribution will approach coincidence, as shown in Fig. 1(c). The POD will be low, and the POFA will be high.

It is clear that the performance capability of a given NDE procedure is dependent on the nature and distribution of the signal outputs generated under the conditions of application. It is also clear that the threshold acceptance criterion applied in the discrimination process is an important factor in the successful application of a procedure. Consider the application of an NDE procedure to a large flaw under conditions that produce a significant separation of probability density distributions of signal and noise, as shown in Fig. 3. If the threshold acceptance criterion (represented by the vertical arrow) is placed at too high a level (Fig. 3a), some of the flaws will be missed (reduce POD). If the acceptance criterion is placed at a proper level (Fig. 3b), clear discrimination will result (high POD). If the acceptance criterion is placed too low (Fig. 3c), all of the flaws will be rejected; but some false alarms will result, and good parts will be rejected (high POFA).

Fig. 3 Influence of acceptance criterion (vertical arrow) on process discrimination. (a) Acceptance criterion too high. (b) Acceptance criterion at proper level. (c) Acceptance criterion too low

The NDE procedure performance characteristics of primary importance are the signal-to-noise ratio (separation margin) and the threshold acceptance criteria applied in the discrimination process. Optimum NDE procedure performance can be obtained by characterizing an NDE procedure and by matching the threshold acceptance criteria to the performance capabilities of the NDE procedure. Such characterization also enables the assessment and quantification of risks that result from changes in acceptance criteria.

Reference Standards. Historically, reference standards for NDE methods of defect detection have been used to ensure the reproducibility of the application of the method(s) and to establish an acceptable quality of the process rather than to establish the dimensions or other applicable parameter of the defect or anomaly. Some methods (such as those used for thickness gaging or electrical conductivity determination) were able to provide an extremely accurate measurement of the appropriate parameter, usually by extrapolation between two known and closely spaced reference standards representative of the condition to be determined. The remaining methods, as typified by radiography, offer at best only a crude estimate of the dimensions, orientation, shape, or other characteristics of the detected defects.

The primary reason for not using reference standards for the quantitative evaluation of defects was, and still is, that the NDE methods respond to most of the parameters of a defect simultaneously; in most cases, there is no way to separate the response from a single parameter, or there is not an accurate response to a single parameter in other cases. Consider, for example, the case of penetrant inspection. The indications formed are usually greater in length, width, or area than the discontinuity present because of the flow of the penetrant material out of the discontinuity during development. When this excess material is removed and the indication is viewed as it starts to appear again, the full length of the discontinuity, if it is linear, will initially not be revealed, because the ends provide little or no penetrant for formation of the indication. As the indication continues to form, it will eventually reach the same length as the discontinuity and will then continue to grow as additional penetrant flows to the surface. This lack of response to the extremities of a discontinuity is common to all NDE methods and illustrates the difficulties associated with using NDE methods for sizing defects.

Quantitative NDE, however, requires that a good estimate be made of the defect size that is detected or, more important, the size of the largest defect that might be left in the part. Because the NDE methods, by the laws of physics, are

inherently inaccurate in sizing, the only available approach is to make a conservative estimate of the size of the defects that can remain. The approach requires a second type of standard used along with the conventional reference standards. This second type, called a qualification standard, contains defects that represent the worst case for both flaw detection and crack growth (generally a surface fatigue crack). Fatigue cracks have the advantages that they can be grown in the laboratory and, when produced under well-controlled conditions, have predictable geometries. The qualification standards are then used in sets to define the lower limit of the flaw size that a given NDE process can reliably detect. The conventional reference standards are used to control the NDE process; therefore, once the qualification standards establish the process sensitivity, the reference standards can be used to ensure that the sensitivity is maintained. Consequently, there are certain requirements that reference standards must meet.

First, reference standards must produce a response comparable to that produced by the smallest qualification standard flaw that is considered reliably detectable. This comparability includes not only response to the flaw itself but also the geometry in which the flaw is contained. In the ultrasonic method, for example, the response to a fatigue crack located in the center of a flat plate can be far different from the response to the same size crack that is located in the bore of a large-diameter hole. Consequently, application of the ultrasonic method for inspection of the two geometries requires qualification standards as well as reference standards for both geometries.

Second, reference standards for a specific inspection must be relatable to other reference standards used for the same inspection. That is, when several reference standards are available, the responses for each one must be known, and more important, the differences in responses for the standards must be known so that adjustments can be made in the inspection to ensure that a uniform process sensitivity can be maintained. Ideally, the responses of all reference standards for a given inspection should be identical; however, from a practical standpoint this is impossible to achieve. As stated previously, the response of the NDE methods is from a multitude of parameters associated with a given discontinuity.

For example, if an electrically discharge machined slot is selected as a defect for a reference standard for an ultrasonic inspection, exact control over the size of the slot in each standard is not sufficient to guarantee identical responses. Slight variations in the orientation of the slot with respect to the surface of the standard and in the surface finish of the slot itself can cause noticeable differences in the ultrasonic response. This is the worst case; other NDE methods vary in their response to subtle geometric parameters, with the magnetic particle and penetrant methods probably being the most tolerant. However, even these methods are highly sensitive to the width of the flaw used in a reference standard.

Another important property of reference standards is durability. Both the material and the type of flaw in a reference standard must be selected so that the standard will not readily deteriorate or change in the environment in which it will be used. These selections are affected by the NDE method for which the standard is intended. Both ultrasonic and penetrant methods are very sensitive to the presence of foreign material inside the flaw. For ultrasonics, this can affect the amount of energy that is reflected from the flaw. For penetrant inspection, the quantity of penetrant that can enter the defect, and consequently the brightness of the indication, will be reduced. The foreign material may be fluids, soils, or corrosion products. For these reasons, magnesium, ferritic steels, and aluminum are particularly poor choices for reference standards for penetrant inspection and require some type of protection if used as ultrasonic standards.

Eddy current methods are not affected by foreign material in the flaw, but are very sensitive to such surface conditions as scratches, pitting, and corrosion. Magnetic particle methods are sensitive to the width of the defect and to anything, such as cold working, that may change the magnetic permeability of the standard. Radiographic methods are sensitive to the thickness of the standard and to changes in the shape of the flaw. In general, a good choice of material for any method is one that is reasonably hard and forms an adherent, tough, and stable surface oxide layer (such as a titanium or nickel-base alloy), thus providing protection against mechanical damage and the gradual buildup of corrosion products.

Personnel. Unless the inspection process is fully automated, the proficiency of the inspection personnel is the largest variable affecting inspection reliability. This proficiency varies widely not only from inspector to inspector but also with the same inspector, depending on his working environment and his mental condition. For fully automated inspections, the proficiency of the inspector in operating the equipment is important but has little or no impact on inspection reliability.

The first task in addressing the contribution of the inspector to inspection reliability is to ensure that he is knowledgeable of the specific techniques to be used and has the basic proficiency to perform the inspection to the required reliability. Experience has demonstrated that the previous qualifications of the inspector--for example, certification to MIL-STD-410D (Ref 1)--are not sufficient to ensure the desired performance with a new inspection that must be performed with high reliability. Therefore, the most straightforward way to assess proficiency is to require inspector participation in the demonstration of inspection reliability. All inspectors that will be required to perform the inspection should also participate. This not only establishes the reliability of the proposed inspection but also identifies those personnel requiring

additional training or experience before they can be expected to perform adequately. Careful observation of the inspector during the demonstration and of the results obtained is necessary to identify the additional training or experience needed. After training and/or additional experience is acquired, the demonstration effort can be repeated to indicate if the inspector has become sufficiently proficient in the inspection technique.

After basic inspection proficiency has been demonstrated, it becomes a supervisory task to ensure that this proficiency is maintained. Control of the work environment of the inspector is important. Distractions such as noise, extremes in temperature, and other irritants should be eliminated to the extent possible. Break periods should be frequent enough to reduce fatigue. Personnel who are ill or otherwise physically impaired should be temporarily assigned other tasks to the extent possible. Other efforts that improve or maintain a good mental attitude are excellent ways to ensure sustained inspection reliability. These include providing acceptable materials and equipment with which to conduct the inspection. Finally, when it is not possible to provide a consistently conducive environment for a highly reliable inspection, two inspectors can perform the same inspection independently to achieve higher reliability than can be obtained with a single inspector. Two inspectors generally will not make identical mistakes.

Applications of NDE Reliability to Systems

Ward D. Rummel, Martin Marietta Astronautics Group; Grover L. Hardy and Thomas D. Cooper, Wright Research & Development Center, Wright-Patterson Air Force Base

NDE Engineering

The difference between NDE engineering and the classical engineering disciplines result from the variety of problems and the indirect nature of NDE measurements on engineering system performance. The functional performance of most NDE methods can be measured, controlling parameters can be documented, and performance output can be modeled; however, the interaction of the NDE method with the test object necessitates the generation of new response parameters and characteristics for many new applications. In addition, variations in material properties, geometry, surface condition, access, or environmental conditions may modify the NDE responses. Therefore, NDE engineering is an essential element of critical engineering system design, qualification, acceptance, and life cycle management. A critical design is not complete until the NDE engineering has been performed and NDE system/process performance validated to functional design requirements and acceptance criteria levels.

Procedure Selection/Development. Trade studies to identify and select candidate NDE procedures are needed for establishing the most economical and reliable procedure that meets acceptance requirements. The process may be satisfied by the assessment of prior art and applications to similar problems or may require research and development of totally new procedures. For demanding applications, a combination of complementary NDE procedures may be required to meet the acceptance criteria objectives. One or more methods can be further characterized and assessed to ensure that the performance objectives, NDE performance margins, NDE costs, engineering system performance risks, and the risks of NDE system/process false alarms can be balanced in overall engineering system management.

System/Process Performance Characteristics. Although care, discipline, and control measures are applied to ensure a consistent output from an NDE system or process, the output will vary within the established control parameters and as a result of slight variations in engineering hardware materials properties, geometry, surface condition, and so on. If repetitive applications are made, a probability density distribution of signal/image output will be generated. This distribution is similar to that obtained by repetitive measurements of a dimension such as a hole diameter or the length of a bolt.

Nondestructive measurements are usually indirect, and positive signals may be generated from nonrelevant sources, such as surface roughness, grain structure, and geometry variations. Such signals constitute the application noise inherent in a specific NDE process or procedure. Discrimination of NDE signal/image outputs must be derived from those signal

levels/amplitudes that exceed the level of the application noise (Fig. 1). Analysis of signal and signal plus noise are common in electronic devices, optics, and other discrimination processes. Similarly, the signal-to-noise margin (ratio) is a primary factor in establishing the level of discrimination of an NDE procedure. Signal/noise reduction procedures can be used to enhance the overall performance of an NDE procedure. However, it is important to recognize that the dominant noise source in an NDE process is not electronic noise that may be reduced by filtering, multiple sampling, and averaging techniques, but is instead the noise due to nonrelevant signals generated in applying the NDE procedure to a specific hardware element.

Fig. 1 Signal/noise density distribution for a large flaw (a), a medium flaw (b), and a small flaw (c)

Conditional Probability in NDE Discrimination. Nondestructive evaluation involves the measurement of complex parameters with inherent variations in both the measurement process and the test object. The output from such a measurement/decision process can be analyzed as a problem in conditional probability. When an NDE assessment is performed for the purpose of crack detection, the outcome is not a simple accept/reject (binary) process, as is frequently envisioned. It is actually the product of conditional acceptance due to the interdependence of the measurement and decision responses. Figure 2 shows the four possible outcomes that result from the application of NDE procedure for crack detection. As shown in Fig. 2, the possible outcomes from an inspection process are:

- *True positive* (TP): A crack exists and is detected, where $M(A,a)$ is the total number of true positives and $P(A,a)$ is the probability of a true positive
- *False positive* (FP): No crack exists but one is identified, where $M(A,n)$ is the total number of false positives and $P(A,n)$ is the probability of a false positive
- *False negative* (FN): A crack exists but is not detected, where $M(N,a)$ is the total number of false negatives and $P(N,a)$ is the probability of a false negative
- *True negative* (TN): No crack exists and none is detected, where $M(N,n)$ is the total number of true negatives and $P(N,n)$ is the probability of a true negative

The interdependence of these matrix quantities can be expressed as:

$M(A,a) + M(N,a) =$ (TP) and (FN) outcomes giving the total opportunities for positive calls (Total number of defects)

and

$M(A,n) + M(N,n) =$ Total opportunities for false alarms from the possible (FP) and (TN) outcomes

		Inspection stimuli	
		Positive, a	Negative, n
Inspection response	Positive, A	True positive (fl原因 detected) $M(A,a)$ $P(A,a)$ (no error)	False positive (false alarm) $M(A,n)$ $P(A,n)$ (type II error)
	Negative, N	False negative (undetected flaw) $M(N,a)$ $P(N,a)$ (type I error)	True negative (no flaw) $M(N,n)$ $P(N,n)$ (no error)

Fig. 2 Matrix of four possible outcomes from an NDE procedure for flaw detection

Because of the interdependent relationship, only two independent probabilities need be considered to quantify the inspection/decision task. The probability of detection (POD) or probability for a true positive $P(A,a)$ can be expressed as:

$$P(A,a) = \frac{M(A,a)}{M(A,a) + M(N,a)} \text{ or } \frac{\text{Total true positive calls}}{\text{Total number of defects}}$$

Similarly, the probability of false alarms (POFA) or the probability for a false positive $P(A,n)$ can be expressed as:

$$P(A,n) = \frac{M(A,n)}{M(A,n) + M(N,n)} \text{ or } \frac{\text{Total false alarms}}{\text{Opportunities for false alarms}}$$

Signal/Noise Relationships. The desired results of the application of NDE procedure are crack detection (signal present) or crack nondetection (signal absent). The basis for detection is that of sensing a signal response and determining that the signal response is above a predetermined threshold. Both sensing and interpretation are dependent on the signal (plus noise) and the noise (application background or response to nonrelevant parameters) that are subjected to the discrimination media (programmed machine discriminator or human operator).

If an NDE procedure is repetitively applied to a single flaw of a given size (in a part with a fixed geometry, surface condition, and so on), the output responses can be used to plot probability density distributions of both flaw signal and application noise responses. Under ideal conditions, such as the response from a large flaw, the signal and noise distributions will be well separated, as shown in Fig. 1(a).

The discrimination of flaw responses from application noise responses is a simple process; POD will be high, and the POFA will be low. In practical engineering applications, the flaw size is not fixed (and is rarely large), and the discrimination process is more complex. Indeed, the discrimination process is applied to a continuous range of flaw sizes, where the capability for discrimination is dependent on the inherent performance characteristic of the NDE procedure and on the separation of the signal (plus noise) from the noise response of the process.

If the NDE procedure is applied to a single flaw of intermediate size (in a part with the same fixed surface finish, geometry, and so on), the output responses can be used to generate probability density distributions for signal and noise, as shown in Fig. 1(b). For this flaw size, the distributions overlap (in part), and the capability for discrimination is dependent on the response from a single set of output signals within these distributions. If the single set has output signals that are well separated (that is, signals at the outer extremes of the distributions), the output response will be interpreted as acceptable (no flaw condition) for those cases where the threshold response acceptance level is located between the signal and noise signals. If the single set of outputs lies at the inner extremes of the distributions, the output response may be interpreted as acceptable (no flaw or undetected flaw condition) or may be interpreted as unacceptable (false alarm condition) for the same threshold response acceptance level. For this condition, the POD will be lower and the POFA will be higher than for the case of discrimination with positive signal/noise separation margins. If the process is repeated for a small flaw (under the same operating conditions), the signal and noise response distribution will approach coincidence, as shown in Fig. 1(c). The POD will be low, and the POFA will be high.

It is clear that the performance capability of a given NDE procedure is dependent on the nature and distribution of the signal outputs generated under the conditions of application. It is also clear that the threshold acceptance criterion applied in the discrimination process is an important factor in the successful application of a procedure. Consider the application of an NDE procedure to a large flaw under conditions that produce a significant separation of probability density distributions of signal and noise, as shown in Fig. 3. If the threshold acceptance criterion (represented by the vertical arrow) is placed at too high a level (Fig. 3a), some of the flaws will be missed (reduce POD). If the acceptance criterion is placed at a proper level (Fig. 3b), clear discrimination will result (high POD). If the acceptance criterion is placed too low (Fig. 3c), all of the flaws will be rejected; but some false alarms will result, and good parts will be rejected (high POFA).

Fig. 3 Influence of acceptance criterion (vertical arrow) on process discrimination. (a) Acceptance criterion too high. (b) Acceptance criterion at proper level. (c) Acceptance criterion too low

The NDE procedure performance characteristics of primary importance are the signal-to-noise ratio (separation margin) and the threshold acceptance criteria applied in the discrimination process. Optimum NDE procedure performance can be obtained by characterizing an NDE procedure and by matching the threshold acceptance criteria to the performance capabilities of the NDE procedure. Such characterization also enables the assessment and quantification of risks that result from changes in acceptance criteria.

Reference Standards. Historically, reference standards for NDE methods of defect detection have been used to ensure the reproducibility of the application of the method(s) and to establish an acceptable quality of the process rather than to establish the dimensions or other applicable parameter of the defect or anomaly. Some methods (such as those used for thickness gaging or electrical conductivity determination) were able to provide an extremely accurate measurement of the appropriate parameter, usually by extrapolation between two known and closely spaced reference standards representative of the condition to be determined. The remaining methods, as typified by radiography, offer at best only a crude estimate of the dimensions, orientation, shape, or other characteristics of the detected defects.

The primary reason for not using reference standards for the quantitative evaluation of defects was, and still is, that the NDE methods respond to most of the parameters of a defect simultaneously; in most cases, there is no way to separate the response from a single parameter, or there is not an accurate response to a single parameter in other cases. Consider, for example, the case of penetrant inspection. The indications formed are usually greater in length, width, or area than the discontinuity present because of the flow of the penetrant material out of the discontinuity during development. When this excess material is removed and the indication is viewed as it starts to appear again, the full length of the discontinuity, if it is linear, will initially not be revealed, because the ends provide little or no penetrant for formation of the indication. As the indication continues to form, it will eventually reach the same length as the discontinuity and will then continue to grow as additional penetrant flows to the surface. This lack of response to the extremities of a discontinuity is common to all NDE methods and illustrates the difficulties associated with using NDE methods for sizing defects.

Quantitative NDE, however, requires that a good estimate be made of the defect size that is detected or, more important, the size of the largest defect that might be left in the part. Because the NDE methods, by the laws of physics, are inherently inaccurate in sizing, the only available approach is to make a conservative estimate of the size of the defects that can remain. The approach requires a second type of standard used along with the conventional reference standards. This second type, called a qualification standard, contains defects that represent the worst case for both flaw detection and crack growth (generally a surface fatigue crack). Fatigue cracks have the advantages that they can be grown in the laboratory and, when produced under well-controlled conditions, have predictable geometries. The qualification standards are then used in sets to define the lower limit of the flaw size that a given NDE process can reliably detect. The conventional reference standards are used to control the NDE process; therefore, once the qualification standards establish the process sensitivity, the reference standards can be used to ensure that the sensitivity is maintained. Consequently, there are certain requirements that reference standards must meet.

First, reference standards must produce a response comparable to that produced by the smallest qualification standard flaw that is considered reliably detectable. This comparability includes not only response to the flaw itself but also the geometry in which the flaw is contained. In the ultrasonic method, for example, the response to a fatigue crack located in the center of a flat plate can be far different from the response to the same size crack that is located in the bore of a large-diameter hole. Consequently, application of the ultrasonic method for inspection of the two geometries requires qualification standards as well as reference standards for both geometries.

Second, reference standards for a specific inspection must be relatable to other reference standards used for the same inspection. That is, when several reference standards are available, the responses for each one must be known, and more important, the differences in responses for the standards must be known so that adjustments can be made in the inspection to ensure that a uniform process sensitivity can be maintained. Ideally, the responses of all reference standards for a given inspection should be identical; however, from a practical standpoint this is impossible to achieve. As stated previously, the response of the NDE methods is from a multitude of parameters associated with a given discontinuity.

For example, if an electrically discharge machined slot is selected as a defect for a reference standard for an ultrasonic inspection, exact control over the size of the slot in each standard is not sufficient to guarantee identical responses. Slight variations in the orientation of the slot with respect to the surface of the standard and in the surface finish of the slot itself can cause noticeable differences in the ultrasonic response. This is the worst case; other NDE methods vary in their response to subtle geometric parameters, with the magnetic particle and penetrant methods probably being the most tolerant. However, even these methods are highly sensitive to the width of the flaw used in a reference standard.

Another important property of reference standards is durability. Both the material and the type of flaw in a reference standard must be selected so that the standard will not readily deteriorate or change in the environment in which it will be used. These selections are affected by the NDE method for which the standard is intended. Both ultrasonic and penetrant methods are very sensitive to the presence of foreign material inside the flaw. For ultrasonics, this can affect the amount of energy that is reflected from the flaw. For penetrant inspection, the quantity of penetrant that can enter the defect, and consequently the brightness of the indication, will be reduced. The foreign material may be fluids, soils, or corrosion

products. For these reasons, magnesium, ferritic steels, and aluminum are particularly poor choices for reference standards for penetrant inspection and require some type of protection if used as ultrasonic standards.

Eddy current methods are not affected by foreign material in the flaw, but are very sensitive to such surface conditions as scratches, pitting, and corrosion. Magnetic particle methods are sensitive to the width of the defect and to anything, such as cold working, that may change the magnetic permeability of the standard. Radiographic methods are sensitive to the thickness of the standard and to changes in the shape of the flaw. In general, a good choice of material for any method is one that is reasonably hard and forms an adherent, tough, and stable surface oxide layer (such as a titanium or nickel-base alloy), thus providing protection against mechanical damage and the gradual buildup of corrosion products.

Personnel. Unless the inspection process is fully automated, the proficiency of the inspection personnel is the largest variable affecting inspection reliability. This proficiency varies widely not only from inspector to inspector but also with the same inspector, depending on his working environment and his mental condition. For fully automated inspections, the proficiency of the inspector in operating the equipment is important but has little or no impact on inspection reliability.

The first task in addressing the contribution of the inspector to inspection reliability is to ensure that he is knowledgeable of the specific techniques to be used and has the basic proficiency to perform the inspection to the required reliability. Experience has demonstrated that the previous qualifications of the inspector--for example, certification to MIL-STD-410D (Ref 1)--are not sufficient to ensure the desired performance with a new inspection that must be performed with high reliability. Therefore, the most straightforward way to assess proficiency is to require inspector participation in the demonstration of inspection reliability. All inspectors that will be required to perform the inspection should also participate. This not only establishes the reliability of the proposed inspection but also identifies those personnel requiring additional training or experience before they can be expected to perform adequately. Careful observation of the inspector during the demonstration and of the results obtained is necessary to identify the additional training or experience needed. After training and/or additional experience is acquired, the demonstration effort can be repeated to indicate if the inspector has become sufficiently proficient in the inspection technique.

After basic inspection proficiency has been demonstrated, it becomes a supervisory task to ensure that this proficiency is maintained. Control of the work environment of the inspector is important. Distractions such as noise, extremes in temperature, and other irritants should be eliminated to the extent possible. Break periods should be frequent enough to reduce fatigue. Personnel who are ill or otherwise physically impaired should be temporarily assigned other tasks to the extent possible. Other efforts that improve or maintain a good mental attitude are excellent ways to ensure sustained inspection reliability. These include providing acceptable materials and equipment with which to conduct the inspection. Finally, when it is not possible to provide a consistently conducive environment for a highly reliable inspection, two inspectors can perform the same inspection independently to achieve higher reliability than can be obtained with a single inspector. Two inspectors generally will not make identical mistakes.

Applications of NDE Reliability to Systems

Ward D. Rummel, Martin Marietta Astronautics Group; Grover L. Hardy and Thomas D. Cooper, Wright Research & Development Center, Wright-Patterson Air Force Base

Applications (Case Studies)

Airframes. In the aerospace industry, the first application of quantitative NDE in a production facility was on airframe structures. Loss of an F-111 aircraft by the propagation of an undetected manufacturing defect led to the incorporation of fracture control in the design and qualification of aircraft structure by the United States Air Force. This was first applied rigorously to the B-1 aircraft and consisted of:

- The identification of critical structural components whose failure would cause the loss of aircraft

- The identification of those areas in the critical structural components experiencing the highest stresses defined
- The estimation of the maximum size of a rogue defect in these areas that could exist without growing to failure in twice the estimated design life

The maximum acceptable size of a rogue defect was established as 6.4 mm (0.250 in.) long by 3.2 mm (0.125 in.) deep for a surface flaw, or 1.3×1.3 mm (0.050×0.050 in.) for a corner crack in a bolt hole or a structural edge. For an embedded flaw, the size was a 6.4 mm (0.250 in.) diam circle. These sizes were selected because experience had shown that they were large enough to be readily detected during production inspection. If the crack sizes that the designer selected for his structure were to be smaller, the capability of the production NDE facility to find the smaller cracks reliably would have to be demonstrated. For the B-1, the crack sizes for many of the critical structural members was smaller than those suggested. Redesign of the components to tolerate the larger, suggested flaws would have resulted in unacceptable weight penalties; consequently, the B-1 production NDE facility was subjected to the first quantitative NDE capability evaluation.

A conservative approach was taken in the design of the NDE reliability demonstration program. Fatigue cracks were selected to represent manufacturing defects for surface and corner flaws, and voids created by diffusion bonding were to serve as embedded defects. Flat panels were the geometries selected, either single panels for surface defect areas or panel stackups for fastener hole areas, and rectangular blocks housed the embedded defects. The materials were aluminum, titanium, and steel. The surface finish for the specimens was the same as for production parts. The methods to be demonstrated were penetrant inspection for all materials with surface flaws, magnetic particle for steel panels with surface flaws, eddy current for all materials with bolt holes, and ultrasonic for titanium and steel embedded flaws. The surface and corner flaws were divided into four groups based on size (Table 1). Because of the difficulty of manufacturing embedded flaws, only two sizes were selected: 1.3 mm (0.050 in.) diam circle and a 1.3×2.5 mm (0.050×0.100 in.) ellipse.

Table 1 Groups of manufactured flaws used to demonstrate the reliability of NDE methods in the B-1 program

Group	Length range		Depth range	
	mm	in.	mm	in.
Surface flaws				
1	0.75-1.91	0.03-0.075	0.25-0.90	0.01-0.035
2	1.92-2.55	0.076-0.100	0.50-1.25	0.020-0.050
3	2.56-3.81	0.101-0.150	0.50-1.80	0.020-0.070
4	3.83-6.35	0.151-0.250	0.50-3.0	0.020-0.12
Group	Bore length range		Radial depth range	
	mm	in.	mm	in.
Corner flaws				

1	0.75-1.53	0.03-0.060	0.25-0.76	0.01-0.030
2	1.54-2.55	0.061-0.100	0.78-1.27	0.031-0.050
3	2.56-3.56	0.101-0.140	1.29-1.78	0.051-0.070
4	3.58-5.0	0.141-0.20	1.80-2.5	0.071-0.10

For every flawed specimen presented to an inspector, at least two unflawed specimens would also be included. Sizing of the defects was not required, and no penalties were assessed if the inspector identified a flaw that did not exist. In addition, if the desired reliability was achieved for a given size range, it also had to be met at the next higher range. The reliability criterion was established to be a 90% probability of detection at the 95% confidence level (CL). This would be considered to be met for the largest flaw size in the given ranges if the following detection requirements were met:

Number of observations	Misses
29	0
46	1
61	2
75	3
89	4
103	5

A variety of lessons were learned during the demonstration program. The production inspection processes used at the time were unable to meet the design requirements of 1.3 mm (0.050 in.) depth for corner cracks. The processes were refined and the documentation was completely rewritten before the requirements were met. Second, not all inspection personnel were capable of achieving the required reliability, even with the refined procedures and documentation. As a result, the demonstration program also became a qualification requirement for personnel that would inspect fracture-critical components. Etching was also required before the penetrant inspection could meet the requirements for any of the materials. Embedded flaws could only be produced for titanium. Table 2 summarizes the results demonstrated for the B-1 production NDE facilities at the reliability criterion of a 90% POD at 95% CL.

Table 2 Results of production NDE facilities in the B-1 program

Method	Material	Flaw type	Flaw depth
--------	----------	-----------	------------

			mm	in.
Penetrant	Aluminum	Surface	0.90	0.035
	Titanium	Surface	0.90	0.035
	Steel	Surface	1.0	0.040
Magnetic particle	Steel	Surface	1.25	0.050
Ultrasonic, shear	Titanium	Embedded	0.9	0.035
	Steel	Embedded	1.25	0.050
Ultrasonic, longitudinal	Titanium	Embedded	1.17	0.046
Eddy current	All	Corner	0.75	0.030

Fracture control, with the resultant quantitative NDE requirement, has been incorporated into the design of every Air Force aircraft since the B-1. In addition, designs already in existence at the time have been analyzed to determine which inspections would be required in service to ensure attainment of the design life of a particular system. Generally, where the suggested flaw sizes mentioned above could not be tolerated, the assumed design flaw for new designs has been a 0.75 mm (0.030 in.) corner crack and a surface flaw with a depth of 1.25 mm (0.050 in.) and a length of 2.5 mm (0.100 in.). The analysis of existing designs, however, has required the assumption of even smaller design flaws. These instances of having to detect smaller flaws in service have been few, and fortunately, identification of the requirement has occurred in sufficient time to allow adequate NDE engineering to address the problems and explore various noninspection options.

Gas Turbine Engines. Following the successful application of damage tolerance concepts and designs to Air Force aircraft structures, attention began to focus on aircraft gas turbine engines. The reason is that the failure of a high-energy (rotating) component in an aircraft gas turbine engine usually results in catastrophic consequences for that engine. Although most engines are designed to contain failure of the blades, the fracture of a disk or spacer will result in destruction of the engine and can cause significant damage to adjacent structures, such as fuel tanks, major structural members, or other engines. Even the contained failure of a blade can cause immediate engine shutdown, which can also have catastrophic consequences for a high-performance, single-engine fighter. Therefore, the integrity of many high-performance components in gas turbine engines is critical to aircraft safety.

As part of an effort to increase the reliability and reduce the costs of operating and maintaining gas turbine engines for the U.S. Air Force, a program known as the Engine Structural Integrity Program (ENSIP) has evolved over the last few years. Its objective is to establish an approach to defining the structural performance, design, development, verification, and life management requirements for new engines for Air Force aircraft. Military standard MIL-STD-1783 defines ENSIP and is currently being applied to the development of all new engines for the Air Force (Ref 2). The document is written in a generic format so that it can be tailored for use by specific System Program Offices to define an engine that will satisfy their own needs. An accompanying handbook is attached as an appendix to provide specific guidance on the rationale, background criteria, lessons learned, and instructions necessary to tailor specific sections of the standard for application. The technical approach is similar to the Aircraft Structural Integrity Program (ASIP), which is defined in MIL-STD-1530 and which has been successfully used for several years in the design of airframes for Air Force systems (Ref 3).

One of the most significant differences between ENSIP and the traditional approaches used in designing engine structures is the requirement to apply damage tolerance and durability criteria to critical components. This requires the designer to assume that flaws exist in the engine structure as manufactured and then to design the critical parts so that the flaws

cannot grow to the size that will cause failure in the lifetime of the part or at least within some predetermined inspection interval. It also establishes life management requirements and procedures to ensure that the necessary inspections capable of finding flaws in the size range used in design are conducted and that the engine parts are sufficiently durable so that the economic life of the engine is acceptable.

The impact of this approach on the inspection community is very significant. Based on the estimated capability of state-of-the-art inspection methods and procedures, many improvements have had to be made both in manufacturing and depot practice to satisfy the intent of ENSIP. Furthermore, to allow the full implementation of this approach, the problem of defining available inspection capability in quantitative terms must continue to receive attention. Acceptable procedures are being established so that it is possible to define exactly how sensitive the inspection methods are on a statistical basis.

The first application of this technology by the Air Force was made to an already designed and operational aircraft gas turbine engine. The F-100 engine, designed and built by Pratt & Whitney, was already widely used in the dual-engine F-15 and the single-engine F-16 aircraft when, in 1978, a durability and damage tolerance assessment effort was initiated. This engine was selected because it was to be purchased in large numbers for Air Force applications for many years to come and because it was a high-performance machine that was very demanding of materials and designs. The costs of owning and operating this system could quickly become untenable if problems developed that significantly limited the life of critical parts or caused significant down-time for repairs. Following the pattern that had been established for applying ASIP to airframes, a joint Air Force/Pratt & Whitney team was formed to work on-site at the facilities of the contractor to complete the analysis and to provide a viable Force Structural Maintenance Plan that could be implemented at the San Antonio Air Logistics Center, where maintenance responsibility for the engines resided.

After the team was in place and the necessary analytical studies were started, it was recognized early in the program that a quantitative understanding of the inspection procedures used in the manufacture of the engine was lacking and that a reliable definition of the largest flaw that could escape detection during manufacture had never been determined. Qualitative statements were made expressing confidence in the inspection methods used, based on the good performance of the engines to that time. It was acknowledged, however, that the fleet was still young and that a quantitative definition of the inspection process was urgently needed.

To fill that need, a joint Air Force Materials Laboratory/Pratt & Whitney effort was established to prepare specimens with known flaws in selected size ranges that would allow quantitative determination of the capability of the inspection methods to be established. The specimens were designed to contain flawed areas in geometrical features that simulated the real areas in the actual hardware. These included holes, the edges of holes, radii, and flat surfaces. Small flaws were generated by damaging the surface, initiating and growing a fatigue crack, and then removing the damaged area until only the desired depth of the flaw that remained was used to produce the specimens. During 1979, some 39 sets of specimens with the desired geometries were fabricated from nickel- and titanium-base alloys for the program. Target crack depths of 0.13, 0.25, and 0.50 mm (0.005, 0.010, and 0.020 in.) with a nominal 3:1 aspect ratio were prepared. Similar specimens with no flaws were also included in each set. The specimens were to be used not only to determine the capability of the manufacturing inspection methods but also to provide guidance concerning the establishment of inspection methods to be used in the depot during maintenance. Fluorescent penetrant inspection and eddy current procedures were evaluated using these specimens. The specimen sets were evaluated by both laboratory and production inspectors.

Because this was the first documented attempt to fabricate flawed specimens of this complexity, a great deal of experience was gained, not only in specimen preparation but also in evaluating the effectiveness of the inspection methods. Fluorescent penetrant inspection was included because, at the time, it was the most extensively applied inspection method used in both manufacturing and depot maintenance. Eddy current methods were included because they had the best potential for finding the very small surface-connected flaws of concern. Based on the work done in this program, the following conclusions were reached:

- The capability of fluorescent penetrant inspection to find small flaws with confidence was affected by many variables, including surface condition, nature of the flaw, the process used and the extent to which it was controlled, and the skills and abilities of the inspectors. The process did not have the necessary reliability to detect very small flaws in many of the critical areas that had been defined
- Eddy current methods appeared to have the best potential for detecting small flaws with the confidence level required
- Eddy current technology and procedures developed in the program could also be adequately automated to make this method viable for use in the depot inspection environment. They could also be adapted for

manufacturing

As a result of this study, the decision was made to implement semiautomated eddy current inspection methods at the San Antonio Air Logistics Center to provide reliable inspection of defined areas in selected critical parts. A facility was established at the depot to allow the inspection of critical components as they were cycled through the depot. The eddy current equipment designed by Pratt & Whitney and incorporated into the facility has been demonstrated to have the capability of finding 0.13 mm (0.005 in.) deep flaws with a reliability of 90% POD at 95% CL.

The second application of damage tolerance analysis involved the TF-34 engine, which powers the A-10 ground-support attack aircraft and the S-3A antisubmarine aircraft. In this case, an Air Force/General Electric team was formed at the General Electric Aircraft Engine Business Group facility in May 1981. Once again, a critical part of the assessment activity was to establish the level of quality built into the parts during the years the engines were manufactured. This was needed to provide an indication of the largest flaw that could have been missed by the inspection methods being used at the time. Because production of the engine was essentially completed by the time the assessment started, the only impact that establishing improved NDE procedure could have was on the methods being used at the maintenance and overhaul depot.

In the case of the TF-34 engine, depot responsibility had been assigned to the Navy and was conducted at the Naval Air Newark Facility in Alameda, CA. Once again, the assessment determined that to achieve acceptable inspection intervals for certain critical rotating components, inspection methods more sensitive and reliable than fluorescent penetrant inspection would be required. A special clean room containing eddy current equipment was established at Alameda to allow inspection of the engine disks and spacers that were considered to be the most critical. The equipment selected for this room was the Eddy Current II system developed under an Air Force Materials Laboratory manufacturing technology contract by the General Electric Company. In addition, the fluorescent penetrant inspection facility at Alameda was upgraded to make it more reproducible and reliable. Inspections have been conducted with these systems since 1984.

Other applications of this technology by the U.S. Air Force have been made to all new gas turbine engines now being used. This includes the F-101 engine in the B-1B and the F-110 engine in the F-16. New engines now being designed for Air Force applications will also incorporate ENSIP technology and will therefore have quantitative inspection capabilities as an integral part of their development. Additional information on ENSIP is available in the article "Fracture Control Philosophy" in this Volume.

Space Shuttle Program. Design requirements for the space shuttle program of the National Aeronautics and Space Administration included the use of fatigue and fracture mechanics principles in all systems designs. The implementation of fatigue and fracture mechanics requires knowledge of the quantitative performance capabilities of the materials, components, and systems acceptance methods. For this application, Rummel *et al.* introduced the concepts of statistical assessments of NDE process performance capabilities (Ref 4). Fatigue cracks in 2219-T87 aluminum alloy were selected as the test specimens for the assessment of various NDE methods. Test specimens were prepared by inducing fatigue cracks of varying size in aluminum alloy sheet specimens (fatigue crack growth from electrodischarge machined starter notches), by machining the specimen surfaces to produce a surface that was representative of production conditions, and by passing the specimens through various NDE procedures and measuring the success in crack detection for the various procedures and operating conditions. The concept of probability of detection as a function of flaw size was introduced, and the performance level of the various NDE procedures was quantified as summarized below.

The experimental test sequence for data gathering, including nondestructive testing (NDT), is shown in Fig. 5. The test specimens were given a precrack (starter notches) that enabled the growth of fatigue cracks of varying size and aspect ratio. A total of 328 cracks were grown in 118 specimens, with flaw length ranging from 0.3 to 18 mm (0.012 to 0.700 in.). The specimens were subjected to x-ray radiographic, liquid penetrant, ultrasonic, and eddy current procedures in the as-machined, after-etch, and after-proof-test conditions. The resulting POD curves for machined and etched surfaces are also shown in Fig. 6.

Fig. 5 Experimental test analysis sequence

Fig. 6 POD plots for four different NDE methods on the same set of specimens. (a) Penetrant inspection. (b) Ultrasonic inspection. (c) Eddy current inspection. (d) X-ray inspection

The precision in crack sizing was also measured, and the results are shown in Fig. 7. The composite threshold detection results were reduced to a plot, as shown in Fig. 8. These data were further simplified to produce the design limits, as shown in Fig. 9. Figure 9 contains design limits for standard NDE and special NDE. The use of special NDE to meet difficult design constraints requires actual demonstration of the performance capabilities of the proposed NDE procedures and a system of controls to ensure that the performance conditions are maintained. These design limits, set by actual NDE performance demonstration, were used as the basis for design and risk management for all space shuttle system components. Assessments and NDE performance capability demonstrations have been continued with space shuttle contractors for all systems production and revalidation.

Special Inspection Systems. As a result of the evolution of damage tolerance requirements, special equipment has been developed in the last few years for increasing the reliability of inspection operations by automating the process and by incorporating computerized data generation and control. This has significantly reduced the dependence on human operators, thus eliminating one of the major sources of error in the process. Most of these automation efforts have been directed toward the inspection of critical aircraft gas turbine engine hardware, primarily in the maintenance depot environment. The systems could be used equally effectively in manufacturing operations. The following are examples of the systems that have been developed over recent years.

Structural Assessment Testing Applications. The NDE performance requirements for overhaul and revalidation of the structural integrity of aircraft engine components (United States Air Force facilities) required the use of special, controlled methods to meet meantime between overhaul and life cycle performance requirements. Special equipment, fixturing, procedures, and personnel training are implemented at the San Antonio Air Logistics Center at Kelly Air Force Base to approach the imposed design constraints. Assessment, demonstration, and validation of the system performance capabilities and reliabilities were necessary to ensure that design requirements were being met.

The special NDE methods were successful in meeting design requirements, and new levels of understanding and performance were gained by the implementation of advanced NDE methods and controls in this special facility. The most significant output from the assessment of these processes was the demonstration of the need for excellence in NDE engineering in validating NDE procedures and in setting acceptance limits. The performance capability of an eddy current method with an acceptance threshold limit set at 3.0 mV is shown in Fig. 10(a). The performance level of the same procedure (same data) with an acceptance limit set at 0.5 mV is shown in Fig. 10(b). This example clearly illustrates the importance of fully characterizing the NDE procedure and managing the NDE procedure within achievable acceptance limits.

Integrated Blade Inspection System. The quantitative assessment of process performance capabilities and process characterization is absolutely necessary in implementing automated NDE systems. At a gas turbine overhaul facility, for example, quantitative assessment methods were applied to the implementation of an integrated blade inspection system with an automated fluorescent penetrant inspection module (Fig. 11). The processed blades are introduced into a robotic

handling system that manipulates the blade in a high-gain optical-laser scan readout system to produce a digitized image of the fluorescent penetrant indications. A computerized data processing and image analysis system provides the readout and decision processing to accept or reject the blades.

Fig. 11 Flow diagram of an automated fluorescent penetrant inspection system

The optical performance capabilities of the readout system enable the detection of very small indications of varying brightness level. The performance of the system is therefore limited by the fluorescent process capabilities and by the pattern recognition capabilities of the system. Signal/noise distributions must be addressed by the decision discrimination process, as shown in Fig. 12. Actual signal/noise distributions measured for the system are shown in Fig. 13. If the discrimination threshold is set too low, a high false call rate will reduce the effectiveness of the automated process. A balance of discrimination at an acceptable false call rate is used to achieve the figure of merit of performance level (Fig. 14) for the system. Signal/noise distribution data can be used to manage the overall process at any desired discrimination/false call level. The process can be modeled to establish performance at varying discrimination levels, as shown in Fig. 15. Quantification and characterization of process parameters are essential for the design, implementation, and management of automated NDE processes.

Retirement-For-Cause (RFC) Inspection Equipment. As described previously, the concept of removing critical rotating components from gas turbine engines because of the initiation of an actual flaw rather than on the basis of an arbitrarily selected time period has already saved the Air Force significant sums of money. One of the key technologies

that has allowed the RFC concept to be accepted has been the development of an accurate, repeatable, reliable inspection system capable of finding very small flaws in the parts. The RFC system, developed under an Air Force Manufacturing Technology contract, has been in operation at the San Antonio Air Logistics Center at Kelly Air Force Base since late 1986. It was developed under a contract with Systems Research Laboratories, and although applied specifically to parts for the F-100 engine (used in the F-15 and F-16 aircraft), it was designed to be sufficiently flexible to inspect parts from any gas turbine engine. This capability was achieved through the use of a team of subcontractors on the program that included Pratt & Whitney, General Electric, Garrett, and Allison.

Eddy current methods for surface flaw detection and ultrasonic methods for detecting embedded flaws were the two inspection techniques selected for the RFC system. Significant advances had been made in automating eddy current inspection through the development of the Eddy Current II system by the General Electric Company on earlier Air Force Manufacturing Technology contracts. These stand-alone automated eddy current devices are in use at the Alameda Naval Air Rework Facility, as previously discussed; the Oklahoma City Air Logistics Center; the General Electric Manufacturing facility in Evandale, OH; and other commercial overhaul facilities. The technology developed and proved in these systems provided an excellent base for the evolution of the more complex RFC system.

The RFC inspection system, which is housed in the special facility shown in Fig. 16, consists of an operator console, a system computer, and eddy current and ultrasonic inspection stations. The operator console is used to monitor the operational status of the system, to track inspection status at each NDE station, and to generate inspection data reports. The system computer performs advanced data processing, system-wide communication, and sophisticated high-speed mathematical and scientific data analyses critical to the inspection process. The NDE inspection stations perform the automated part inspections, flaw detection, and signal-preprocessing activities. The system functions essentially independent of any human operator input, with the exception of loading and unloading the parts to be inspected onto the stations.

Fig. 16 Retirement-for-cause inspection facility

When the system was installed, a series of critical tests was conducted to establish its flaw size detection capability and reliability. Tests included automatic scans of engine disks and a statistically significant number of representative fatigue-cracked test specimens. Rivet hole inspection data showed a 90% POD with a 95% CL at the 100 μm (4 mil) crack depth range. Bolt hole and flat surface data indicated reliable detection in the desired 125 to 250 μm (5 to 10 mil) depth range. A strong correlation between apparent versus actual flaw depth data was seen in all test data. The ultrasonic inspection data were similarly encouraging. Examples of POD at 95% CL generated for various geometrical configurations are shown in Fig. 17. A similar facility is to be installed at the Air Force engine maintenance depot at the Oklahoma City Air Logistics Center at Tinker Air Force Base.

Introduction

INSPECTION SYSTEMS are inevitably driven to their extreme capability for finding small flaws. When applied at this extreme, not all flaws of the same size will be detected. In fact, repeat inspections of the same flaw will not necessarily produce consistent hit or miss indications, and different flaws of the same size may have different detection probabilities. Because of this uncertainty in the inspection process, capability is characterized in terms of the probability of detection (POD) as a function of flaw size, a . At present, the function $POD(a)$ can be estimated only through inspection reliability experiments on specimens containing flaws of known size. Further, statistical methods must be used to estimate the parameters of the $POD(a)$ function and to quantify the experimental error in the estimated capability.

The methods for analyzing NDE reliability data have undergone a considerable evolution since the middle of the 1970s. Formerly, a constant probability of detection of all flaws of a given size was postulated, and binomial distribution methods were used to estimate this probability and its lower confidence bound (Ref 1, 2). This nonparametric method of analysis produced valid statistical estimates for a single flaw size, but required very large sample sizes to obtain reasonable lower confidence bounds on the probability of detection. In the absence of large numbers of representative specimens with equal flaw sizes, various methods were devised for analyzing data based on grouping schemes. Although the resulting POD appeared more acceptable using these schemes, the lower confidence bounds were no longer valid.

In recent years, an approach based on the assumption of a model for the $POD(a)$ function was devised (Ref 3, 4, 5, 6, 7). Analyses of data from reliability experiments on nondestructive inspection (NDI) methods indicated that the $POD(a)$ function can be reasonably modeled by the cumulative log normal distribution function or, equivalently, the log-logistics (log odds) function. The parameters of these functions can be estimated using maximum likelihood methods. The statistical uncertainty in the estimate of NDI reliability has traditionally been reflected by a lower (conservative) confidence bound on the $POD(a)$ function. The asymptotic statistical properties of the maximum likelihood estimates can be used to calculate this confidence bound. Details of the mathematics for these maximum likelihood calculations are presented in this article.

Statistical Nature of the NDE Process

In the application of an NDE method there are many factors that can influence whether or not the inspection will result in the correct decision as to the absence or presence of a flaw. In general, NDE comprises the application of a stimulus to a structure and the interpretation of the response to the stimulus. Repeated inspections of a specific flaw can produce different magnitudes of stimulus response because of minute variations in setup and calibration. This variability is inherent in the process. Different flaws of the same size can produce different response magnitudes because of differences in material properties, flaw geometry, and flaw orientation. The interpretation of the response can be influenced by the capability of the interpreter (manual or automated), the mental acuity of the inspector as influenced by fatigue or emotional outlook, and the ease of access and the environment at the inspection site. All these factors contribute to inspection uncertainty and lead to a probabilistic characterization of inspection capability.

There are two related approaches to a probabilistic framework for analyzing inspection reliability data. Originally, inspection results were recorded only in terms of whether or not a flaw was found. Data of this nature are called hit/miss data, and an analysis method for this data type evolved from the original binomial characterization (Ref 3, 4, 5). It was later observed that there is more information in the NDE signal response from which the hit/miss decision is made (Ref 6). Because the NDE signal response can be considered to be the perceived flaw size, data of this nature are called \hat{a} data. A second analysis method was developed based on \hat{a} data (Ref 7). Although the analysis frameworks are based on data of different natures, the hit/miss data can be obtained from \hat{a} data. Both methods are based on the same model for the $POD(a)$ function, but different results will be obtained if the two analysis methods are applied to the same data set. The following sections present the two approaches to formulating the $POD(a)$ function.

POD(a) From Hit/Miss Data. In typical NDE reliability studies, relatively few inspections are performed on each flaw in the specimen set. Table 1 presents an example of hit/miss results from fluorescent penetrant inspections by 3 inspectors on 35 cracks in flat plate specimens. Because there are only three inspections, it is impossible to obtain more than a general impression of any change in the chances of crack detection as the cracks get larger. In a study for the Air Force (Ref 3), inspections of cracked specimens were independently conducted by large numbers of inspectors around the country. The data from this program provided considerable insight into the nature of the probability of crack detection.

Table 1 Example of summary data sheet of hit/miss results

The example is based on the fluorescent penetrant inspection of flat plates by three inspectors.

(a) 1 indicates crack was found; 0 indicates crack was not found.

Figure 1 shows the results of eddy current inspections by 60 different inspections of a set of 41 cracks around countersunk fastener holes in a 1.5 in (5 ft) segment of a C-130 center wing box (Ref 3). Each data point represents the proportion of times that the crack was found. This data set, which is representative of such available data sets, clearly indicates that:

- The chances of detection are correlated with crack size
- Different cracks of the same size can have significantly different crack detection probabilities
- Factors other than size are affecting the chances of detection

Data of this nature also provide the analysis framework for characterizing NDE reliability for the general hit/miss data set.

Fig. 1 Example crack detection probabilities from 60 eddy current inspections of each crack

The $POD(a)$ function is defined as the proportion of all cracks of size a that will be detected in a particular application of an NDE system. Assume that each crack of size a in the potential population of cracks has its own distinct crack detection probability, p , and that the probability density function of the detection probabilities is given by $f_a(p)$. Figure 2 shows a schematic representation of this density. The conditional probability of a randomly selected crack from the population having detection probability of p and being detected at the inspection is given by $p f_a(p) dp$. The unconditional probability of a randomly selected crack from the population being detected is the sum of the conditional probabilities over the range of p , that is:

$$POD(a) = \int_0^1 p f_a(p) dp \quad (\text{Eq 1})$$

Therefore, $POD(a)$ is the average of the detection probabilities for cracks of size a .

Fig. 2 Schematic of distribution of detection probabilities for cracks of fixed length

Equation 1 implies that the $POD(a)$ function is the curve through the averages of the individual density functions of the detection probabilities. This curve is the regression equation and provides the basis for testing assumptions about the applicability of various $POD(a)$ models. In Ref 4, seven different functional forms were tested for applicability to available POD data, and it was concluded that the log-logistics (log odds) function best modeled the data and provided an acceptable model for the data sets of the study. Note that the log odds model is commonly used in the analysis of binary (hit/miss) data because of its analytical tractability and its close agreement with the cumulative log normal distribution (Ref 8).

Two mathematically equivalent forms of the log odds model have subsequently been used. The earliest form is given by:

$$POD(a) = \frac{\exp(\alpha + \beta \ln a)}{1 + \exp(\alpha + \beta \ln a)} \quad (\text{Eq 2})$$

This parametrization can also be expressed as:

$$\ln \left[\frac{POD(a)}{1 - POD(a)} \right] = \alpha + \beta \ln(a) \quad (\text{Eq 3})$$

In the Eq 3 form, the log of the odds of the probability of detection (the left-hand side of Eq 3) is expressed as a linear function of $\ln(a)$ and is the source of the name of the log odds model. Note that given the results of a large number of independent inspections of a large number of cracks, the parameters of the model can be fit with a regression analysis. As an example, Fig. 3 shows Eq 3 fit to the data of Fig. 1. This regression approach will not be discussed further, because the maximum likelihood estimates (see the section "Analysis of Hit/Miss Data" in this article) can be applied to much smaller samples of inspection results and can give equivalent answers for large sample sizes.

Fig. 3 Example linear relation between log odds of crack detection and log crack size

Although the parametrizations of Eq 2 and 3 are sensible in terms of estimation through regression analyses, α and β are not easily interpretable in physical terms. A mathematically equivalent form of the log odds POD(a) model is given by (Ref 8):

$$\text{POD}(a) = \left\{ 1 + \exp - \left[\frac{\pi}{\sqrt{3}} \left(\frac{\ln a - \mu}{\sigma} \right) \right] \right\}^{-1} \quad (\text{Eq 4})$$

In this form, $\mu = \ln a_{0.5}$, where $a_{0.5}$ is the flaw size that is detected 50% of the time, that is, the median detectable crack size. The steepness of the POD(a) function is inversely proportional to σ ; that is, the smaller the value of σ , the steeper the POD(a) function. The parameters of Eq 2 and 4 are related by:

$$\mu = \frac{-\alpha}{\beta} \quad (\text{Eq 5})$$

$$\sigma = \frac{\pi}{(\beta \sqrt{3})} \quad (\text{Eq 6})$$

The log odds $POD(a)$ function is practically equivalent to a cumulative log normal distribution with the same parameters, μ and σ of Eq 4. Figure 4 compares the log odds and cumulative log normal distribution functions for $\mu=0$ and $\sigma=1$. Equation 4 is the form of the log odds model that will be used in the section "Analysis of Hit/Miss Data" in this article.

Fig. 4 Comparison of log odds and cumulative log normal models

POD(a) From Signal Response Data. The NDE flaw indications are based on interpreting the response to a stimulus. In eddy current or ultrasonic systems, the response might be a peak voltage referenced to a calibration. In fluorescent penetrant inspections, the response would be a combination of brightness and size of the indication. Assume the response can be quantified and recorded in terms of a parameter, \hat{a} , that is correlated with flaw size. Then \hat{a} summarizes the information for determining if a positive flaw indication will be given. Only if \hat{a} exceeds a defined decision threshold, \hat{a}_{dec} , will a positive indication be given.

As an example of the concept, Table 2 summarizes the results of highly automated eddy current inspections of 28 cracks in flat plate specimens. The three data sets resulted from the use of three probes, with all other factors held constant. The values in Table 2 are the depth of each crack and the peak voltage in counts recorded by the system. Figure 5 shows a plot of the \hat{a} versus a data for probe A. No signal was recorded for 2 of the cracks, because their \hat{a} values were below the recording signal threshold, \hat{a}_{th} . These points are indicated by a down arrow at \hat{a}_{th} , indicating that the response was at an indeterminable value below the recording signal threshold. Similarly, \hat{a} for 5 of the cracks exceeded the saturation limit, \hat{a}_{sat} , of the recording system. These points are indicated by an up arrow at \hat{a}_{sat} , indicating that the response was at an indeterminable value above the recording saturation limit. In Fig. 5, the decision threshold is set at 250 counts. Only those cracks whose \hat{a} value is above 250 would have been flagged (detected).

Table 2 Example of a summary data sheet of \hat{a} versus a data

The example is based on eddy current inspections of flat plates.

(a) Peak voltage below the recording level threshold

Fig. 5 Example inspection signal response as a function of crack depth

The $POD(a)$ function can be obtained from the relation between \hat{a} and a . If $g_a(\hat{a})$ represents the probability density of the \hat{a} values for fixed crack size a , then:

$$POD(a) = \int_{\hat{a}_{dec}}^{\infty} g_a(\hat{a}) d\hat{a} \quad (\text{Eq 7})$$

This calculation is illustrated in Fig. 6, in which the shaded area under the density functions represents the probability of detection.

Fig. 6 Schematic of $POD(a)$ calculation from \hat{a} versus a relation

In general, the correlating function between \hat{a} and a defines the mean of $g_a(\hat{a})$, that is:

$$\hat{a} = \mu(a) + \delta \quad (\text{Eq 8})$$

where $\mu(a)$ is the mean of $g_a(\hat{a})$ and δ is a random error term accounting for the differences between \hat{a} and $\mu(a)$. The distributional properties of δ determine the probability density $g_a(\hat{a})$ about $\mu(a)$, as will be shown.

In the \hat{a} data analyzed to date, a linear relation between $\ln(\hat{a})$ and $\ln(a)$ with normally distributed deviations has proved satisfactory (for example, Fig. 5). This model is expressed by:

$$\ln(\hat{a}) = \beta_0 + \beta_1 \ln(a) + \delta \quad (\text{Eq 9})$$

where δ is normally distributed with zero mean and constant standard deviation, σ_δ . Data have been observed that flatten at the large crack sizes. However, because the decision threshold was far below the non-linear range, restricting the range of cracks to smaller sizes permitted the application of Eq 9. The normality of δ has proved to be an acceptable assumption.

Assuming that the \hat{a} versus a relation is modeled by Eq 9 and that δ is normally distributed with zero mean and standard deviation of σ_δ , the $POD(a)$ function is calculated as:

$$\begin{aligned}
\text{POD}(a) &= \text{Probability } [\hat{a} > \hat{a}_{\text{dec}}] \\
\text{POD}(a) &= \text{Probability } [\ln(\hat{a}) > \ln(\hat{a}_{\text{dec}})] \\
\text{POD}(a) &= 1 - \Phi \left[\frac{\ln(\hat{a}_{\text{dec}}) - \beta_0 + \beta_1 \ln(a)}{\sigma_{\delta}} \right]
\end{aligned} \tag{Eq 10}$$

where Φ is the standard normal distribution function. Using the symmetry properties of Φ , Eq 10 can be reduced to:

$$\text{POD}(a) = \Phi \left\{ \frac{\ln(a) - [\ln(\hat{a}_{\text{dec}}) - \beta_0]/\beta_1}{\sigma_{\delta}/\beta_1} \right\} \tag{Eq 11}$$

Equation 11 is a cumulative log normal distribution function with mean and standard deviation of log crack length given by:

$$\mu = \frac{\ln(\hat{a}_{\text{dec}}) - \beta_0}{\beta_1} \tag{Eq 12}$$

$$\sigma = \frac{\sigma_{\delta}}{\beta_1} \tag{Eq 13}$$

In the section "Signal Response Analysis" in this article, maximum likelihood methods for estimating β_0 , β_1 , and σ_{δ} from \hat{a} versus a data will be presented. Note that the \hat{a} values below the recording threshold and above the saturation limit must be properly accounted for in these analyses. Note also that data from multiple inspections of the same cracks require analysis methods that are dependent on the design of the reliability experiment. Methods for placing lower confidence bounds on the estimated $\text{POD}(a)$ function using the sampling distributions of the maximum likelihood estimates of β_0 , β_1 , and σ_{δ} are also included in the section "Signal Response Analysis."

Design of NDE Reliability Experiments

An NDE reliability experiment comprises a test matrix of inspections on a set of specimens with known flaw locations and sizes. The specimens are inspected under conditions that simulate as closely as practical the actual application conditions. The experimental design determines the test matrix, and there are four major analysis concerns to be addressed in the experimental design. These are:

- The method of controlling the factors to be evaluated in the experiment
- The method of accounting for the uncontrolled factors in the experiment
- The number of flawed and unflawed inspection sites
- The sizes of the flaws in the specimens

These topics are addressed in the following sections.

Controlled and Uncontrolled Factors

The primary objective of NDE reliability experiments has been to demonstrate efficacy for a particular application by estimating the $POD(a)$ function and its lower 95% confidence bound. (Although NDE reliability experiments can also be conducted to optimize a system, analyses to meet this objective are beyond the scope of this article.) To demonstrate capability, it is assumed that the protocol for conducting the inspections is well defined for the application, that the inspection process is under control (hit/miss decisions are stable over time), and that all other factors introducing variability into the inspection decision will be representative of the application. The representativeness of these other factors can be ensured either by controlling the factors during the inspection or randomly sampling the factors to be used in the experiment. The methods of accounting for these factors are important aspects of the statistical design of the experiment and significantly influence the statistical properties of the estimates of the $POD(a)$ function parameters. Of particular note in this regard is that k inspections on n flaws is not equivalent to inspections on $n \cdot k$ different flaws, even if the inspections are totally independent.

The most important of the factors introducing variation are:

- Differences in physical properties of cracks of nominally identical sizes
- The basic repeatability of the magnitude of the NDE signal response when a specific crack is independently inspected by a single inspector using the same equipment
- The summation of all the human factors associated with the particular inspectors in the population of interest
- Differences introduced by changes in inspection hardware

These factors must be addressed explicitly or implicitly in every NDE reliability experiment.

In general, the specimens used in NDE reliability experiments are very expensive to obtain and characterize in terms of the sizes of the flaws in the specimens. Therefore, each experiment is based on one set of specimens containing flawed and unflawed inspection sites. Because the results are significantly influenced by the specimens, it must be assumed that the flaws are representative of those that will be present in the structural application. If other factors are to be included in the experiment, they will be based on repeated inspections of the same flaws. From a statistical viewpoint, this restriction on the experimental design limits the sample size to the number of flaws in the specimen set. Because different cracks of the same size can have significantly different crack detection probabilities, multiple inspections of the same crack provide information about the detection probability of only that crack.

The generality of the capability characterization is limited to the application for which the experiment is representative. Either important factors must be typical of the application or random samples must be chosen from the population of interest and repeat inspections performed for these factors. For example, if a single inspector is used to characterize a fluorescent penetrant inspection, it must be assumed that this inspector is typical of all the inspectors in the shop. An alternative might be to choose a random sample of inspectors from the total pool and have each of the selected inspectors perform the experiment.

Depending on the application of the results of the experiment, stratified sampling may be required to obtain a representative sample. For instance, if the capability will apply to two facilities and one of them inspects twice as many components as the other, then that facility should have twice as many inspectors in the experiment. An alternative method is to characterize each facility independently. Care is then required in combining the results for the joint characterization.

Factorial Experiments for Hit/Miss Data. The analysis for the hit/miss data requires that all factors be balanced in any one analysis. When practical, this can be most easily achieved by performing complete factorial experiments. For example, Table 1 contains the results of a two-factor experiment, with the factors being cracks and inspectors. These data can be analyzed as one data set with three inspections per crack. The resulting $POD(a)$ function and its confidence bound would be representative of the population of inspectors from which the sample was drawn.

If the effect of a third factor, for example, different lots of penetrants, were to be included, the entire experiment would be repeated for each of the lots chosen at random from the population of all lots. If three lots were sampled, a total of nine inspections would be performed on each of the flawed specimens, and the resulting $POD(a)$ would apply to the entire inspection process. Suppose, however, that the second and third samples of penetrant were used only by Inspector A. In this case, the two additional sets of inspection data cannot be combined with the other three in a single analysis, because the triple representation of Inspector A would bias the resulting $POD(a)$ function toward his specific capability. The three sets of inspection results for Inspector A can be combined, but the range of applicability of the answer is limited to Inspector A (unless it can be shown or assumed that Inspector A is representative of the entire population).

When many factors must be considered, the number of possible combinations in a factorial experiment can easily become prohibitive. More sophisticated experimental designs (fractional replications, for example) may then be required. In such cases, the assistance of a professional statistician is recommended.

Experimental Design for \hat{a} Data. Inspection-result data in the \hat{a} form contain considerably more information than hit/miss data and, as a consequence, permit more flexibility in the design of the experiment. In \hat{a} analysis, the parameters of the $POD(a)$ function are estimated from the slope, intercept, and standard deviation of residuals of the $\ln(\hat{a})$ versus $\ln(a)$ relation, as given by Eq 9, 12, and 13. In Eq 9, δ can be considered to be the sum of random effects, and experiments can be designed to estimate the components of the total variation in δ . For example, operators, probes, and repeatability can be jointly evaluated in a factorial experiment and their effects accounted for in the estimate of $POD(a)$. The statistical model for this experiment would be:

$$\ln(\hat{a}) = \beta_0 + \beta_1 \ln(a) + C_i + O_j + P_k + R_l + (\text{interaction terms}) \quad (\text{Eq 14})$$

where C_i , O_j , P_k , and R_l are the random effects due to cracks, operators, probes, and repeats, respectively. The random term, δ of Eq 9, is the sum of all random effects. It can be assumed that the mean and variance of random effect X are zero and σ_x^2 , respectively. Then:

$$\sigma_\delta^2 = \sigma_C^2 + \sigma_O^2 + \sigma_P^2 + \sigma_R^2 + \dots \quad (\text{Eq 15})$$

Therefore, β_0 and β_1 can be estimated from a regression analysis, and σ_δ can be estimated from the components of variance using the expected mean squares for the random effects.

In principle, any statistical design from which the components of variance can be estimated can be used in an \hat{a} NDE reliability experiment. However, the analysis methods would be specific to the particular design, and it is beyond the scope of this article to address the general problem. In the section "Signal Response Analysis" in this article, it will be

assumed that only the variation due to cracks and one other factor is being investigated. It is recommended that the assistance of a qualified statistician be obtained for more sophisticated experimental designs.

Sample Sizes and Flaw Sizes

Sample sizes in NDE reliability experiments are driven more by the economics of specimen fabrication and characterization than by the desired degree of precision in the estimate of the $POD(a)$ function. Although apparently reasonable $POD(a)$ functions can often be obtained from applying the maximum likelihood analysis to relatively few test results, the confidence bound calculation is based on asymptotic (large sample) properties of the estimates. It should be emphasized that the calculations can also produce totally unacceptable results from the relatively few test results or from data that are not reasonably represented by the assumptions of the models. Therefore, there are minimal sample size requirements that must be met to provide a degree of reasonable assurance in the characterization of the capability of the system.

Larger sample sizes in NDE reliability experiments will, in general, provide greater precision in the estimate of the $POD(a)$ function. However, the sample size is determined from the number of cracks in the experiment, and there is a coupling with the flaw sizes that must also be considered. The effect of this coupling manifests itself differently for the hit/miss and \hat{a} analyses.

Sample Size Requirements for Hit/Miss Analysis. Data from hit/miss experiments are generally not amenable to testing assumptions regarding the form of the $POD(a)$ model. These tests require either large numbers of independent inspections on each flaw of a specimen set or inspection results from an extremely large number of compatible specimens (Ref 3, 4). Number and size considerations in hit/miss experiments are directed at their effect on the sampling properties of the parameters of the $POD(a)$ function (Ref 9).

In the hit/miss analysis, the output of an inspection states only whether or not a crack of known length was found in the inspection (Table 1). There are probabilities associated with the outcomes, and the analysis assumes that this probability increases with flaw size. Because it has been assumed that the inspection process is in a state of control, there is a range of flaw sizes over which the $POD(a)$ function is rising. In this flaw size range of uncertainty, the inspection system has limited discriminating power in the sense that detecting or failing to detect would not be unusual. Such a range might be defined by the interval $(a_{0.10}, a_{0.90})$, where a_p denotes the flaw size that has probability of detection equal to p ; that is:

$$POD(a_p) = p \quad (\text{Eq 16})$$

Flaws smaller than $a_{0.10}$ would then be expected to be missed, and flaws greater than $a_{0.90}$ would be expected to be detected.

In a hit/miss reliability experiment, flaws outside the range of uncertainty do not provide as much information concerning the $POD(a)$ function as cracks within this range. Cracks in the almost-certain detection range and almost-certain miss range provide very little information concerning probability of detection. Therefore, in the hit/miss experiment, not all flaws convey the same amount of information, and the effective sample size is not necessarily the total number of flaws in the experiment. Adding a large number of very large flaws does not increase the precision in the estimate of the parameters of the $POD(a)$ function.

In a reliability experiment, the location of the increasing range of the $POD(a)$ function is not known. Further, the same sets of specimens are often used in many different experiments. Therefore, it is not possible to fabricate a set of specimens with optimal flaw sizes for a particular experiment. To minimize the chances of completely missing the crack size range of maximum information and to accommodate the multiple uses of specimens, flaw sizes should be uniformly distributed between the minimum and maximum of the sizes of potential interest. A minimum of 60 flaws should be distributed in this range, but as many as economically possible should be used.

Sample Size Requirements for \hat{a} Analysis. The recorded signal response, \hat{a} , provides significantly more information for analysis. In particular, the $POD(a)$ model is derived from the correlation of the \hat{a} versus a data, and the assumptions concerning the $POD(a)$ model can be tested using the signal response data. Further, the pattern of \hat{a} responses can indicate an acceptable range of extrapolation. Therefore, the range of crack sizes in the experiment is not as critical in an \hat{a} analysis as in a hit/miss analysis. For example, if the decision threshold in Fig. 5 were set at 250 counts, all but four of the cracks would have been detected. The larger cracks would have provided little information about the

POD(a) function in a hit/miss analysis. In an \hat{a} analysis, however, all of the recorded \hat{a} values provided full information concerning the relation between signal response and crack size, and the values at the signal threshold and saturation limit provided partial information. The linearity of the fit, the normality of the deviations, and the constancy of the residual variation can all be easily evaluated from the \hat{a} versus a plot.

Because of the added information in the \hat{a} data, it is recommended that at least 30 flaws be present in experiments whose results can be recorded in this form. Increasing the number of flaws increases the precision of the estimates, so the test set should contain as many flawed specimens as economically feasible.

Unflawed Inspection Sites. In the context of the analyses presented in this section, sample size refers to the number of known flaws in the specimens to be inspected. The total specimen set should also contain at least twice this number of unflawed inspection sites. The unflawed sites are necessary to ensure that the NDE procedure is discriminating between flawed and unflawed sites and to provide an estimate of the false call rate.

Although the false call rate can have important economic consequences, the NDE reliability analyses in this section were dictated by the requirements of damage tolerance analyses. The primary objective was to estimate the chances of missing flaws that might lead to structural failures. The concepts of these NDE reliability analyses can be generalized to include a non-zero probability of a flaw indication when no flaw is present at an inspection site, that is, $\text{POD}(a = 0) > 0$.

NDE Reliability Data Analysis

Alan P. Berens, University of Dayton Research Institute

Maximum Likelihood Analysis

Parameter estimation based on the principle of maximizing the likelihood of an observed sample of data is a standard statistical technique and is amply described in the literature (Ref 10, 11). The purpose of this section is to summarize the method and its asymptotic sampling distribution properties in the context of analyzing NDE reliability data. Further, a method for using this information to calculate lower confidence bounds on the POD(a) function is also presented.

Parameter Estimation. Let X_i represent the outcome of the i th inspection and $f(X_i; \theta)$ represent the probability of obtaining X_i , where $\theta = (\theta_1, \theta_2, \dots, \theta_k)'$ is the vector of the k parameters in the probability model. For example, in a hit/miss experiment, X_i would be 0 or 1 with probability defined by Eq 4, where a is the size of flaw i and $\theta = (\mu, \sigma)'$. In an \hat{a} versus a experiment, X_i is the log of the signal response, and $f(X_i; \theta)$ is a normal density function with mean and standard deviation given by $\theta = (\beta_0 + \beta_1 \ln a, \sigma\delta)'$, as defined in Eq 9. Let X_1, \dots, X_n represent the results of independent inspections of n flaws. The likelihood, L , of a specific result is given by the likelihood function:

$$L(\theta) = \prod_{i=1}^n f(X_i; \theta) \quad (\text{Eq 17})$$

For a given outcome of the experiment, X_i is known and Eq 17 is a function of θ . The maximum likelihood estimate is the value, $\hat{\theta}$, which maximizes $L(\theta)$. For the models considered here, it is more convenient to work with the log $L(\theta)$:

$$\log L(\theta) = \sum \log f(X_i; \theta) \quad (\text{Eq 18})$$

which is also maximized at $\hat{\theta}$. The maximum likelihood estimates are given by the solution of the k simultaneous equations:

$$\frac{\partial \log L(\theta)}{\partial \theta_i} = 0, i = 1, \dots, k \quad (\text{Eq 19})$$

Asymptotic Sampling Distribution Properties. For the models being used in NDE reliability studies, the maximum likelihood estimates are invariant, consistent, and efficient. Further, they are asymptotically joint normally distributed with means given by the true parameter values, θ_i , and the variance-covariance matrix defined by:

$$V = I^{-1} \quad (\text{Eq 20})$$

where I is the information matrix whose elements I_{ij} are the expected (E) values:

$$I_{ij} = - E \left[\frac{\partial^2}{\partial \theta_i \partial \theta_j} \log f(X_i; \theta) \right], i, j = 1, \dots, k \quad (\text{Eq 21})$$

In application, the maximum likelihood estimate, $\hat{\theta}$, is substituted for θ in Eq 21. Therefore, given the results of inspecting a large number of flaws and a specific function for the POD(a) model, the parameters of the model can be estimated, and the sampling distribution of the parameters will be joint normal with the known variance-covariance matrix. Examples of these equations for the hit/miss and response signal models are given in the sections "Analysis of Hit/Miss Data" and "Signal Response Analysis," respectively, in this article. In these applications, the assumed models will be the log odds and cumulative log normal distribution functions. However, other models can also be used if evidence is available to support their selection.

Confidence Bounds on the POD(a) Function. Because the POD(a) function is equivalent to a cumulative distribution function and the parameters are being estimated by maximum likelihood, a procedure developed by Cheng and Iles (Ref 12 and 13) can be used to place lower confidence bounds on the POD(a) function. Such bounds are calculated from the variance-covariance matrix of the estimates and reflect the sensitivity of the experiment to both the number and sizes of flaws in the specimens of the experiment.

The assumed POD(a) model is a cumulative log normal distribution function with parameters $\theta = (\mu, \sigma)'$. For distribution functions defined by location and scale parameters (as is the case of the log normal distribution), the information matrix can be written in the form:

$$I(\mu, \sigma) = \frac{n}{\sigma^2} \begin{bmatrix} k_0 & -k_1 \\ -k_1 & k_2 \end{bmatrix} \quad (\text{Eq 22})$$

where n is the number of cracks in the experiment. The lower one-sided confidence bound of the POD(a) function is given by:

$$\text{POD}_\alpha(a) = \Phi(\hat{z} - h) \quad (\text{Eq 23})$$

where $\Phi(z)$ is the standard cumulative normal distribution, and:

$$\hat{z} = \frac{\ln(a) - \hat{\mu}}{\hat{\sigma}} \quad (\text{Eq 24})$$

$$h = \left\{ \frac{\gamma}{n k_0} \left[1 + \frac{(k_0 \hat{z} + k_1)^2}{(k_0 k_2 - k_1^2)} \right] \right\}^{0.5} \quad (\text{Eq 25})$$

where γ is obtained from Table 3 for the number of cracks in the experiment and the desired confidence level.

Table 3 Values of γ for lower confidence bounds on the POD(a) function

Sample size	Confidence level, %

Analysis of Hit/Miss Data

Estimation of the parameters of the log odds model for hit/miss data is based directly on the probability of each 0 or 1 result of an inspection. Assume that a balanced experiment has produced k inspections on each of n cracks. For this application, the likelihood function is given by:

$$L(\mu, \sigma) = \prod_{i=1}^n \prod_{j=1}^k p_i^{Z_{ij}} (1 - p_i)^{1-Z_{ij}} \quad (\text{Eq 26})$$

where $Z_{ij} = 0$ or 1 for the j th inspection of the i th flaw producing a miss or a find, respectively, and the probability of detecting a flaw of size a_i is given by:

$$p_i = \frac{h(a)}{1 + h(a)} \quad (\text{Eq 27})$$

$$h(a) = \exp \left[\frac{\pi}{\sqrt{3}} \left(\frac{\ln(a_i) - \mu}{\sigma} \right) \right] \quad (\text{Eq 28})$$

This form of the $\text{POD}(a)$ function is simply a more convenient algebraic form of Eq 4. The vector of parameters to be estimated is defined by $\theta = (\mu, \sigma)'$.

The log likelihood equation is:

$$\ln L(\mu, \sigma) = \sum_i \sum_j [Z_{ij} \ln(p_i) + (1 - Z_{ij}) \ln(1 - p_i)] \quad (\text{Eq 29})$$

Parameter Estimation in Hit/Miss Analysis. The maximum likelihood estimates are given by the solution to:

$$0 = \frac{\partial \ln L}{\partial \mu} = \sum_i \sum_j \left[\frac{Z_{ij}}{p_i} \frac{\partial p_i}{\partial \mu} + \frac{(1 - Z_{ij})}{(1 - p_i)} \left(\frac{\partial p_i}{\partial \mu} \right) \right] \quad (\text{Eq 30})$$

$$0 = \frac{\partial \ln L}{\partial \sigma} = \sum_i \sum_j \left[\frac{Z_{ij}}{p_i} \frac{\partial p_i}{\partial \sigma} + \frac{(1 - Z_{ij})}{(1 - p_i)} \left(\frac{\partial p_i}{\partial \sigma} \right) \right] \quad (\text{Eq 31})$$

Taking the derivatives and simplifying yields:

$$0 = \sum_i \sum_j \frac{Z_{ij}}{k} - \sum_i \frac{h(a_i)}{1 + h(a_i)} \quad (\text{Eq 32})$$

$$0 = \sum_i \sum_j \frac{Z_{ij}}{k} \ln(a_i) - \sum_i \frac{\ln(a_i) h(a_i)}{1 + h(a_i)} \quad (\text{Eq 33})$$

Any standard computational method, such as the Newton-Rhapson iterative procedure (Ref 14), can be used to find the solutions to Eq 32 and 33.

Because iterative techniques converge to local maxima, the solution to Eq 32 and 33 may be sensitive to the initial values. A set of initial values based on the method of moments has been found to be useful (Ref 7). These are given by:

$$\mu_1 = X_n - \frac{X_1 p_1}{2} - (0.5) \sum_{i=2}^n (X_i - X_{i-1}) (p_i - p_{i-1}) \quad (\text{Eq 34})$$

$$\sigma = \{X_n^2 - \frac{p_1}{2} X_1^2 - \mu_1^2 - (0.5) \sum_{i=2}^n (X_i^2 - X_{i-1}^2) (p_i - p_{i-1})\}^{0.5} \quad (\text{Eq 35})$$

where X_1, \dots, X_n are the ordered values of the natural logs of the flaw sizes and p_i is the observed percentage of detections of the i th ordered flaw size. If convergence is not obtained, increasing the initial estimate of μ has often provided convergence. However, Eq 32 and 33 are not always solvable. This will be discussed further in the section "Comments on Hit/Miss Analysis" in this article.

Confidence Bound Calculation in Hit/Miss Analysis. The information matrix is estimated from Eq 21, using $\hat{\mu}$ and $\hat{\sigma}$ for μ and σ . For this POD(a) model, the elements of the information matrix are given by:

$$I_{11} = \frac{1}{\sigma^2} \left[\frac{\pi^2}{3} \right] \sum_i \frac{h(a_i)}{[1 + h(a_i)]^2} = \frac{n k_0}{\sigma^2} \quad (\text{Eq 36})$$

$$I_{12} = I_{21} = \frac{1}{\sigma^2} \left[\frac{\pi^2}{3\sigma} \right] \sum_i \frac{\ln(a_i) h(a_i)}{[1 + h(a_i)]^2} = \frac{n k_1}{\sigma^2} \quad (\text{Eq 37})$$

$$I_{22} = \frac{1}{\sigma^2} \left[\frac{\pi^2}{3\sigma^2} \right] \sum_i \frac{(\ln a_i)^2 h(a_i)}{[1 + h(a_i)]^2} = \frac{-n k_2}{\sigma^2} \quad (\text{Eq 38})$$

Note that k_0 , k_1 , and k_2 , the parameters required in the calculation of the lower confidence bound on the POD(a) function, are also defined by Eq 36, 37, and 38. All of the parameters required by Eq 23, 24, and 25 to calculate the lower confidence bound on the POD(a) function are available.

Hit/Miss Analysis Examples. As examples of the application of the method to real data, the parameters of the log odds POD(a) function were obtained for the data in Table 1. Table 4 presents a summary of the parameters of the POD(a) function for each data set of Table 1 and the combination of the three data sets in a single analysis. Figure 7 shows the POD(a) function and the lower 95% confidence bound for Inspector A and the same information when the data from the three inspectors are combined. Adding inspections of the same cracks did not increase the precision of the estimate of the POD(a) function. Figure 8 compares the POD(a) functions for the three inspectors and the composite.

Table 4 POD(a) parameters for the hit/miss data in Table 1

Parameter	Inspector			Composite
	A	B	C	
$\hat{\mu}$	0.96	1.11	0.82	0.96
$\hat{\sigma}$	0.59	1.04	0.87	0.88

a_{50} , mm (in.) ^(a)	2.62 (0.103)	3.03 (0.119)	2.27 (0.089)	2.61 (0.103)
a_{90} , mm (in.) ^(b)	5.34 (0.210)	10.6 (0.417)	6.54 (0.257)	7.18 (0.283)
$a_{90/95}$, mm (in.) ^(c)	21.6 (0.850)	232 (9.13)	38.8 (1.53)	51.0 (2.01)

- (a) $a_{50} = \exp(\hat{\mu})$ = estimate of crack size at 50% POD.
- (b) $a_{90} = \exp(\hat{\mu} + 1.282 \hat{\sigma})$ = estimate of crack size at 90% POD.
- (c) $a_{90/95}$ = upper 95% confidence bound on the estimate of a_{90} .

Fig. 7 POD(a) function and lower 95% confidence bound from hit/miss analysis of the data in Table 1 for one inspection per crack (from Inspector A) and for three inspections per crack (from the composite result of Inspectors A, B, and C)

Fig. 8 POD(a) functions from hit/miss analysis of the data in Table 1

Comments on Hit/Miss Analysis. In a well-designed experiment of sufficient sample size for which the log odds model is a reasonable representation of the POD(a) function, the maximum likelihood hit/miss analysis will provide a valid solution. Conversely, lacking any of these elements, it is possible that either no solution or an unacceptable solution can result. If there is no overlap in the flaw size ranges of the detections and misses, Eq 32 and 33 will not yield a solution. More flaws are needed in the region of increase of the POD(a) function. It is also possible to obtain an estimate of a POD(a) function that decreases with flaw size if the inspection system is poorly designed or not in control and if large flaws tend to be missed more often than small flaws. Both of these types of results are readily apparent, albeit disconcerting.

A third type of unacceptable result is an apparently acceptable POD(a) function but a confidence bound that eventually decreases with flaw size. This situation is most easily understood in terms of the log odds versus log flaw size plot. If the slope is positive, the POD(a) function will appear reasonable, but if it is not significantly greater than zero, the lower confidence bound will eventually decrease with flaw size. Therefore, a decreasing confidence bound is evidence of lack of fit of the log odds model.

Finally, lack of fit of the model is often manifest in large values of σ coupled with small values of μ or extremely wide confidence intervals. Although there are, in general, insufficient data in hit/miss experiments to test hypotheses about the POD(a) model, as a minimum each fit should be subjectively judged. For example, in Fig. 9, the observed detection proportions of each crack in the data of Table 1 are superimposed on the composite POD(a) function and confidence limit from Fig. 7. The uncertainty in the POD(a) function as indicated by the width of the confidence bound seems justified by the plot of the raw data. In this example, if greater precision (narrower confidence bounds) were desired, more cracks in the 2 to 8 mm (0.08 to 0.3 in.) range would be needed in the experiment. Such plots provide an indication of the fit of the model to the data as well as the range of flaw sizes that are contributing to the information from which the POD(a)

function is being estimated. This is true even for experiments in which there is only one inspection per crack and all detection probabilities are plotted at 0 or 1.

Fig. 9 Example fit of hit/miss $POD(a)$ function and lower 95% confidence bound to observed detection probabilities (three inspections per crack)

NDE Reliability Data Analysis

Alan P. Berens, University of Dayton Research Institute

Signal Response Analysis

In signal response data analysis, the parameters of the $POD(a)$ function are calculated from parameters of the \hat{a} versus a relation. If all the \hat{a} values are between the signal recording threshold and the saturation limit, a simple regression analysis of $\ln(\hat{a})$ versus $\ln(a)$ will yield the necessary information to estimate the $POD(a)$ function and its lower confidence

bound. In fact, the least squares estimates from the regression analysis also happen to be the maximum likelihood estimates. The analysis presented in this section is applicable to the more general case in which some of the \hat{a} values are censored at the recording threshold or the saturation limit. This more general analysis will give answers identical to those of the regression analysis if all \hat{a} values are available for all of the flaws (Ref 15).

In the response signal analysis, it is assumed that the \hat{a} values for a flaw of size a have a normal distribution, with mean and standard deviation given by:

$$\mu \ln(\hat{a}) = \beta_0 + \beta_1 \ln(a) \quad (\text{Eq 39})$$

$$\sigma \ln(\hat{a}) = \sigma \delta \quad (\text{Eq 40})$$

where $\sigma \delta$ does not depend on the crack size. To simplify the notation, let $Y_i = \ln(\hat{a}_i)$ and $X_i = \ln(a_i)$. The random variable:

$$Z = \frac{Y - (\beta_0 + \beta_1 X)}{\sigma \delta} \quad (\text{Eq 41})$$

has a standard normal distribution. Let $\phi(z)$ represent the density function of the standard normal distribution:

$$\phi(z) = \frac{1}{\sqrt{2\pi}} \exp[-(z^2)] \quad (\text{Eq 42})$$

and $\Phi(z)$ represent the cumulative normal distribution:

$$\Phi(z) = \int_{-\infty}^z \phi(\xi) d\xi \quad (\text{Eq 43})$$

The likelihood function is partitioned into three regions:

- Region R, for which \hat{a} values were recorded
- Region T, for which only a maximum value is known (the \hat{a} values fall below the recording signal threshold and cannot be recorded)
- Region S, for which only a minimum \hat{a} value is known (the \hat{a} values fall above the saturation limit and cannot be recorded)

These regions are identified by the open circles, the down arrows, and the up arrows, respectively, in Fig. 5. The likelihood function for the entire sample is the product of the likelihood functions for the three regions:

$$L(\beta_0, \beta_1, \sigma \delta) = \prod_R L_R \prod_T L_T \prod_S L_S \quad (\text{Eq 44})$$

But (suppressing the dependency of L on β_0, β_1 , and $\sigma \delta$):

$$L_R = \prod_{i=1}^r \frac{1}{\sigma} \phi(Z_i) \quad (\text{Eq 45})$$

$$L_T = \prod_{i=1}^I \Phi_i(a_{th}) \quad (\text{Eq 46})$$

$$L_S = \prod_{i=1}^S [1 - \Phi_i(a_{sat})] \quad (\text{Eq 47})$$

because $1/\sigma \phi(Z_i) dz$ is the probability of observing \hat{a}_i for the i th flaw in R, $\Phi_i(a_{th})$ is the probability of obtaining an \hat{a}_i value below the recording threshold for the i th flaw in S, and $1 - \Phi_i(a_{sat})$ is the probability of obtaining an \hat{a}_i value above the saturation limit for the i th flaw in T. The log of the likelihood function is:

$$\begin{aligned} \ln [L(\beta_0, \beta_1, \sigma)] \\ = -r \ln(\sigma) - \frac{1}{2\sigma^2} \sum_R [Y_i - (\beta_0 + \beta_1 X_i)]^2 \\ + \sum_T \ln \Phi_i(a_{th}) + \sum_S \ln [1 - \Phi_i(a_{sat})] \end{aligned} \quad (\text{Eq 48})$$

where r is the number of cracks in R, that is, the number of cracks for which \hat{a} values were recorded.

Parameter Estimation in \hat{a} Analysis. The maximum likelihood estimates are given by the solutions to:

$$0 = \frac{\partial \ln(L)}{\partial \beta_0} = \frac{1}{\sigma} \left[\sum_R Z_i + \sum_S V(Z_i) - \sum_T W(Z_i) \right] \quad (\text{Eq 49})$$

$$\begin{aligned} 0 &= \frac{\partial \ln(L)}{\partial \beta_1} \\ &= \frac{1}{\sigma} \left[\sum_R Z_i X_i + \sum_S X_i V(Z_i) - \sum_T X_i W(Z_i) \right] \end{aligned} \quad (\text{Eq 50})$$

$$\begin{aligned} 0 &= \frac{\partial \ln(L)}{\partial \sigma} \\ &= \frac{1}{\sigma} \left[-r + \sum_R Z_i^2 + \sum_S Z_i V(Z_i) - \sum_T Z_i W(Z_i) \right] \end{aligned} \quad (\text{Eq 51})$$

where:

$$V(Z_i) = \frac{\phi(Z_i)}{1 - \Phi(Z_i)} \quad (\text{Eq 52})$$

$$W(Z_i) = \frac{\phi(Z_i)}{\Phi(Z_i)} \quad (\text{Eq 53})$$

Standard numerical methods, such as the Newton-Raphson iterative procedure (Ref 14), can be used to find the solutions to Eq 49, 50, and 51. Excellent choices for the initial estimates of iterative procedures are the intercept, slope, and standard deviation of residuals obtained from a standard regression analysis of only those \hat{a} values for which a valid response was recorded.

Confidence Bound Calculation in \hat{a} Analysis. Because the POD(a) parameters are calculated from the estimates of the \hat{a} versus a data, the calculation of the lower confidence bound is a five-step process:

- The information matrix for the estimates of β_0 , β_1 , and $\sigma\delta$ is obtained using Eq 21
- The variance-covariance matrix of $\hat{\beta}_0$, $\hat{\beta}_1$, and $\hat{\sigma}\delta$ is obtained by inverting the information matrix (Eq 20)
- The variance-covariance matrix of the estimates of μ and σ are calculated based on a first-order Taylor series expansion of the equations relating β_0 , β_1 , and $\sigma\delta$ to μ and σ (Eq 12 and 13)
- The information matrix for $\hat{\mu}$ and $\hat{\sigma}$ is obtained by inverting the variance-covariance matrix to obtain Eq 22
- The calculated values are substituted into Eq 23, 24, and 25 to obtain the lower confidence bound

The elements of the information matrix for $\hat{\theta} = (\beta_0, \beta_1, \sigma\delta)$ are given by (dropping the subscripts):

$$I_{11} = \frac{-\partial^2 \log(L)}{\partial \beta_0^2} = \frac{1}{\sigma^2} \left[r + \sum_s \lambda(Z) - \sum_T \psi(Z) \right] \quad (\text{Eq 54})$$

$$\begin{aligned} I_{12} = I_{21} &= \frac{-\partial^2 \log(L)}{\partial \beta_0 \partial \beta_1} \\ &= \frac{1}{\sigma^2} \left[\sum_R X + \sum_s X \lambda(Z) - \sum_T X \psi(Z) \right] \end{aligned} \quad (\text{Eq 55})$$

$$\begin{aligned} I_{13} = I_{31} &= \frac{-\partial^2 \log(L)}{\partial \beta_0 \partial \sigma\delta} \\ &= \frac{1}{\sigma^2} \left[2 \sum_R Z + \sum_s V(Z) + \sum_s Z \lambda(Z) \right. \\ &\quad \left. - \sum_T W(Z) - \sum_T Z \psi(Z) \right] \end{aligned} \quad (\text{Eq 56})$$

$$\begin{aligned} I_{22} &= \frac{-\partial^2 \log(L)}{\partial \beta_1^2} \\ &= \frac{1}{\sigma^2} \left[\sum_R X^2 + \sum_s X^2 \lambda(Z) - \sum_T X^2 \psi(Z) \right] \end{aligned} \quad (\text{Eq 57})$$

$$\begin{aligned} I_{23} = I_{32} &= \frac{-\partial^2 \log(L)}{\partial \beta_1 \partial \sigma\delta} \\ &= \frac{1}{\sigma^2} \left[2 \sum_R XZ + \sum_s XV(Z) + \sum_s XZ \lambda(Z) \right. \\ &\quad \left. - \sum_T XW(Z) - \sum_T XZ \psi(Z) \right] \end{aligned} \quad (\text{Eq 58})$$

$$\begin{aligned}
I_{33} &= \frac{-\partial^2 \log(L)}{\partial \sigma_8^2} \\
&= \frac{1}{\sigma^2} \left[-r + 3 \sum_{\mathbf{R}} Z^2 + 2 \sum_{\mathbf{S}} ZV(Z) + \sum_{\mathbf{S}} Z^2 \lambda(Z) \right. \\
&\quad \left. - 2 \sum_{\mathbf{T}} ZW(Z) - \sum_{\mathbf{T}} Z^2 \psi(Z) \right]
\end{aligned} \tag{Eq 59}$$

$$\lambda(Z) = V(Z) [V(Z) - Z] \tag{Eq 60}$$

$$\psi(Z) = -W(Z) [W(Z) + Z] \tag{Eq 61}$$

Let $V(\hat{\beta}_0, \hat{\beta}_1, \hat{\sigma}_8)$ represent the variance-covariance matrix of the maximum likelihood estimates of the $\ln(\hat{a})$ versus $\ln(a)$ analysis. The value $V(\hat{\beta}_0, \hat{\beta}_1, \hat{\sigma}_8)$ is obtained from the inverse of the information matrix. Let the elements of $V(\hat{\beta}_0, \hat{\beta}_1, \hat{\sigma}_8)$ be defined by:

$$V(\hat{\beta}_0, \hat{\beta}_1, \hat{\sigma}_8) = \begin{bmatrix} \sigma_0^2 & \sigma_{01} & \sigma_{08} \\ \sigma_{01} & \sigma_1^2 & \sigma_{18} \\ \sigma_{08} & \sigma_{18} & \sigma_8^2 \end{bmatrix} \tag{Eq 62}$$

Using a Taylor series expansion about the true values of μ and σ to linearize the relations expressed by Eq 12 and 13, the variance-covariance matrix of $\hat{\mu}$ and $\hat{\sigma}$ is given by (Ref 16):

$$V(\mu, \sigma) = \frac{1}{\beta_1^2} T V(\hat{\beta}_0, \hat{\beta}_1, \hat{\sigma}_8) T \tag{Eq 63}$$

and the transformation matrix T is defined by:

$$T = \begin{bmatrix} 1 & \mu & 0 \\ 0 & \sigma & -1 \end{bmatrix} \tag{Eq 64}$$

Multiplying the matrices yields the variances and covariance of $\hat{\mu}$ and $\hat{\sigma}$ as:

$$\sigma_{\hat{\mu}}^2 = \frac{1}{\beta_1^2} [\sigma_0^2 + 2\hat{\mu}\sigma_{01} + \hat{\mu}^2\sigma_1^2] \tag{Eq 65}$$

$$\sigma_{\hat{\sigma}\hat{\mu}} = \sigma_{\hat{\mu}\hat{\sigma}} = \frac{1}{\beta_1^2} [\hat{\sigma}\sigma_{01} - \sigma_{08} - \hat{\mu}\sigma_{18} + \hat{\mu}\hat{\sigma}\sigma_1^2] \tag{Eq 66}$$

$$\sigma_{\hat{\sigma}}^2 = \frac{1}{\beta_1^2} [\sigma_8^2 - 2\hat{\sigma}\sigma_{18} + \hat{\sigma}^2\sigma_1^2] \tag{Eq 67}$$

Inverting this variance-covariance yields the values of k_0 , k_1 , and k_2 required in Eq 25 to calculate the lower confidence bound on the POD(a) function.

Multiple Inspections Per Flaw. Repeat \hat{a} values for the same flaw can be analyzed to estimate the magnitude of the total variability being introduced by factors other than the flaws in the experiment. In essence, the random term, δ , of Eq 9, can be partitioned into components that can be estimated if the experiment is properly designed. The relative magnitude of the components of variance indicates potential areas for improving the system. However, the methods for using the \hat{a} values to generate POD(a) functions and confidence bounds from complex experiments with censored values are still under development.

If there are no censored \hat{a} values, the following analysis provides valid estimates of both the POD(a) function and its confidence bound. If there are censored \hat{a} values, the POD(a) parameter estimates are valid, but the confidence bound is approximate. Much of the data recorded in the \hat{a} format is from automated systems. In these systems, the variability in \hat{a} values has been dominated by that associated with different flaws. This variability is correctly analyzed in the following analysis. In applications to date, the approximation to account for the secondary sources of variability has been judged to be negligible.

To model an additional source of variability, Eq 9 is rewritten as:

$$\begin{matrix} Y_{ij} = \ln(\hat{a}_{ij}) = \beta_0 + \beta_1 \ln(a_i) + c_i + r_{ij} \\ i = 1, \dots, n \\ j = 1, \dots, k \end{matrix} \quad (\text{Eq 68})$$

where \hat{a}_{ij} represents the j th observation on the i th flaw, c_i is the random deviation of flaw i from the fit, and r_{ij} is the random deviation about c_i introduced by replicate j of the source of the repeated observations. For this model of $\ln(\hat{a})$ versus $\ln(a)$:

$$\delta = c_i + r_{ij} \quad (\text{Eq 69})$$

Because it is reasonable to assume that the variability introduced by flaws is independent of that introduced by other factors:

$$\sigma_\delta^2 = \sigma_c^2 + \sigma_r^2 \quad (\text{Eq 70})$$

where σ_r^2 can be estimated as the pooled-within variance of \hat{a}_i values for each flaw using those flaws for which \hat{a} values were recorded (Ref 17):

$$\hat{\sigma}_r^2 = \frac{\sum_{i=1}^{n^*} \sum_{j=1}^{k_i} (Y_{ij} - \bar{Y}_i)^2}{\sum k_i - n^*} \quad (\text{Eq 71})$$

where n^* is the number of flaws with uncensored \hat{a} values and k_i is the number of uncensored \hat{a} values for flaw i .

Between-crack variability, σ_c^2 , cannot be estimated directly, but can be estimated indirectly from a censored regression analysis. First, the mean log response for each flaw is calculated. This mean response may be a simple average if all \hat{a} values are available, but a mean based on an analysis of censored data (as previously discussed) will be required for the flaws for which \hat{a} values were censored at the decision threshold or saturation limit. The analysis in the section "Parameter Estimation in \hat{a} Analysis" in this article is then used on the model:

$$Y_i = \beta_0 + \beta_1 X_i + c_i + \bar{r} \quad (\text{Eq 72})$$

to obtain estimates $\hat{\beta}_0$, $\hat{\beta}_1$, and $\hat{\sigma}^* \delta$. However:

$$\begin{aligned}\hat{\sigma}_s^{*2} &= \hat{\sigma}_c^2 + \hat{\sigma}_r^2 \\ &= \hat{\sigma}_c^2 + \frac{\hat{\sigma}_r^2}{k}\end{aligned}\quad (\text{Eq 73})$$

Solving Eq 73 for $\hat{\sigma}_c^2$ and substituting into Eq 70 yields:

$$\hat{\sigma}_s^2 = \hat{\sigma}_s^{*2} + \frac{(k-1)}{k} \hat{\sigma}_r^2 \quad (\text{Eq 74})$$

The value $(\hat{\sigma}^*\delta)^2$ is obtained from the censored regression analysis, and $\hat{\sigma}_r^2$ is obtained directly from the $\ln(\hat{a})$ values. Equation 74 provides the estimate of $\sigma\delta$ to be used in the $\text{POD}(a)$ function.

To date, the lower confidence bound has been placed on the $\text{POD}(a)$ function using the information matrix derived from the censored regression through the average of the $\ln(\hat{a})$ values for each crack. This procedure does not account for the added uncertainty resulting from the estimate of $\hat{\sigma}_r^2$. When $\hat{\sigma}_c^2$ is significantly greater than $\hat{\sigma}_r^2$, the error introduced by neglecting this variation is judged to be negligible. (Most of the applications of the \hat{a} analysis have been on highly automated eddy current systems. In these applications, the variability of $\ln(\hat{a})$ values within cracks has been significantly less than that between cracks.) The method of constructing exact confidence bounds is under development. This process can be extended to account for more than one component of the variability of $\ln(\hat{a})$ values.

Examples of \hat{a} Analysis. The data in Table 2 resulted from three eddy current inspections of 28 fatigue cracks in flat plates simulating the web/bore of an aircraft engine disk. The three inspections are from the use of three different probes, with all other factors being held fixed. Table 5 presents a summary of the parameters of the $\text{POD}(a)$ function for each data set in Table 2 and the combination of the three data sets in a single analysis. The $\ln(\hat{a})$ versus $\ln(a)$ data from probe A are presented in Fig. 5. This data set had two inspection results below the recording threshold and five results above the saturation limit. The $\text{POD}(a)$ function for probe A and its lower 95% confidence bound are shown in Fig. 10. The combined results from the three probes yield the composite $\text{POD}(a)$ function and its lower 95% confidence bound, which are also shown in Fig. 10. If the probes were in some sense selected at random from the population of all probes applicable to this equipment and if other factors were assumed to be representative of the application, this composite $\text{POD}(a)$ function would be representative of the inspection system. Figure 11 shows the individual $\text{POD}(a)$ functions for all three probes and their composite.

Table 5 Example of $\text{POD}(a)$ parameters determined from the data in Table 2

The decision threshold is 250 counts.

Parameter	Probe			Composite
	A	B	C	
$\hat{\mu}$	-1.89	-1.80	-2.12	-1.96
$\hat{\sigma}$	0.24	0.23	0.40	0.33
a_{50} , mm (in.) ^(a)	0.15 (0.006)	0.17 (0.007)	0.12 (0.005)	0.14 (0.0055)
a_{90} , mm (in.) ^(b)	0.21 (0.0083)	0.22 (0.009)	0.20 (0.008)	0.21 (0.0083)

- (a) $a_{50} = \exp(\hat{\mu})$ = estimate of crack size at 50% POD.
- (b) $a_{90} = \exp(\hat{\mu} + 1.282\hat{\sigma})$ = estimate of crack size at 90% POD.
- (c) $a_{90/95}$ = upper 95% confidence bound on the estimate of a_{90} .

Fig. 10 POD(a) function and lower 95% confidence bound from signal response analysis of the data in Table 2 with one inspection per crack (with probe A) and with three inspections per crack (from the composite result of probes A, B, and C)

Fig. 11 POD(a) functions from signal response analysis of the data in Table 2

Comments on \hat{a} Analysis. There are several advantages of the \hat{a} analysis over the hit/miss analysis in estimating the POD(a) function. These accrue primarily because of the added information contained in the \hat{a} values.

It is not as critical in the experiment to have flaws with sizes in the range of increase of the POD(a) function. Because the analysis does not depend on whether or not flaws were detected, the decision threshold can be arbitrarily set after the experiment. Even if the recording threshold is close to the decision threshold, the method permits extrapolation of the results from larger flaw sizes to the smaller sizes of interest. The extrapolation is reasonable over the flaw size range for which the $\ln(\hat{a})$ versus $\ln(a)$ relation is linear, and deviations from the fit are normally distributed with constant variance.

A principal advantage of the \hat{a} analysis is that statistical tests of the underlying assumptions are readily available (Ref 17). In most of the experiments that have been analyzed by this method, the assumptions could not be rejected. However, for very large flaws, a tendency for the $\ln(\hat{a})$ versus $\ln(a)$ relation to bend down has been observed on occasion. In this region, the \hat{a} values are very large, and all of the flaws are easily detected. One method of linearizing the $\ln(\hat{a})$ response is to restrict the analysis to a range of smaller flaw sizes by censoring \hat{a} values at a lower saturation limit. This is equivalent to deleting data points and may reduce the sample size to an unacceptable number. In this case, the flaw sizes in the experiment were not appropriate for the application. It should be noted that ignoring this type of nonlinearity tends to produce a nonconservative POD(a) function, because the effect is to produce a smaller value of the median detectable crack size, μ .

When the data do not fit the model, it is possible to obtain results that have no relation to reality. This can occur if $\ln(\hat{a})$ is not an increasing linear function of $\ln(a)$ or if there are outliers in the data set that have a significant influence on the analysis. The effects of these anomalies are sometimes manifested in unreasonable values of μ or a or by a lower

confidence bound that eventually decreases for large crack sizes. As a minimum, it is recommended that a plot of $\ln(\hat{a})$ versus $\ln(a)$ be obtained for all experiments. This will permit at least a subjective judgment concerning the assumptions of the analysis.

If the data do not fit the model, it is necessary to ensure that the process is in control and that the experiment was properly designed and executed. It may also be possible to use other relations between \hat{a} and a as the basis of analysis, but these have not yet been explored.

Models for Predicting NDE Reliability

J.N. Gray, T.A. Gray, N. Nakagawa, and R.B. Thompson, Center for NDE, Iowa State University

Introduction

FRACTURE CONTROL PHILOSOPHIES, as discussed in previous articles in this Section, depend on a damage-tolerant design. The essential feature of such an approach is the incorporation of redundant load paths so that, even if local failures do occur, the structure will be safe for a period of time and can either be removed from service or repaired. Parts containing readily detectable damage can be used if that damage will remain in stable condition until the next inspection opportunity.

The implementation of such an approach requires the knowledge and integration of stress, flaw size, and failure mechanisms. As shown in Fig. 1 for the case in which fatigue can be modeled by linear-elastic fracture mechanics, cyclic stress excursions, $\Delta\sigma$, and flaw size, a , are required as inputs to fracture mechanics to predict a stress intensity range, ΔK . If the stress intensity exceeds a critical value known as the plane-strain fracture toughness, K_{Ic} , catastrophic failure is imminent. Otherwise, crack growth laws of the form $da/dN = A(\Delta K)^m$ (where N is the number of stress excursions and A and m are constants) can be used to estimate the safe life available before catastrophic failure.

Fig. 1 Methodology of lifetime prediction for metal parts undergoing cyclic fatigue. Source: Ref 1

Implementation of this damage-tolerant design approach rests on three methodologies: stress analysis, nondestructive evaluation (NDE), and failure modeling. Incorporation of these methodologies in the design of damage-tolerant

components would ideally take advantage of analytical or numerical computations to model the expected lifetime performance of a component. At present, extensive capabilities are in place for modeling stresses and failures, and these are widely used in the design process. However, the modeling of nondestructive evaluation is not nearly as widely accepted. Instead, frequent use is made of empirical rules based on extensive demonstration programs. For both economic and time reasons, there is a significant need to develop a model base for estimating NDE reliability (which is often measured in terms of the probability of flaw detection at given confidence level). It is the purpose of this article to present the current status and future directions of efforts to develop such a capability. This is not intended as a review of international efforts in NDE reliability modeling but rather as a summary of the authors' experience in modeling the inspectability of aerospace components, with emphasis on engine components. Therefore, attention is given to ultrasonic, eddy current, and radiographic inspection. Broader sets of references for the case of ultrasonics can be found in recent review articles (Ref 2, 3). Of particular note is the work performed by the Central Electricity Generating Board in modeling the inspectability of nuclear power generating components (Ref 4).

The details of models for NDE reliability are partially dictated by their envisioned uses (Ref 5, 6), which are conceptually illustrated in Fig. 2. One would like to have a model that predicts the probability of detecting flaws of various sizes. This would clearly require as inputs the design of the component, its history of processing and service, and a specification of the inspecting methodology to be used. Given the specifications of these input parameters, it could first be asked whether the predicted probability of flaw detection of the NDE system is adequate to meet the demands imposed by the required performance of the component. Should the expected probability of detection (POD) be inadequate, the model could be exercised to modify the specifications of the inspection, the design of the component, or the processing or service profiles. The NDE models thus become an integral part of a broader concept known as unified life cycle engineering or simultaneous engineering (Ref 7). The essential feature is that one should consider all aspects of the life of a component in the design process, including the ability to inspect and maintain the component, rather than just the initial costs. This will ultimately lead to more sophisticated networking of models, as shown in Fig. 3. Figure 3 illustrates a number of factors that must be added to the traditional computer-aided design and manufacturing (CAD/CAM) methodologies to produce a design optimized for life cycle performance. Multiple interactions among the various factors must be considered to allow the design to address simultaneously all the issues associated with damage tolerance (Ref 8).

Fig. 2 Diagram of probability of detection model and its application to NDE system qualification and optimization and to computer-aided design for inspectability. POD, probability of detection

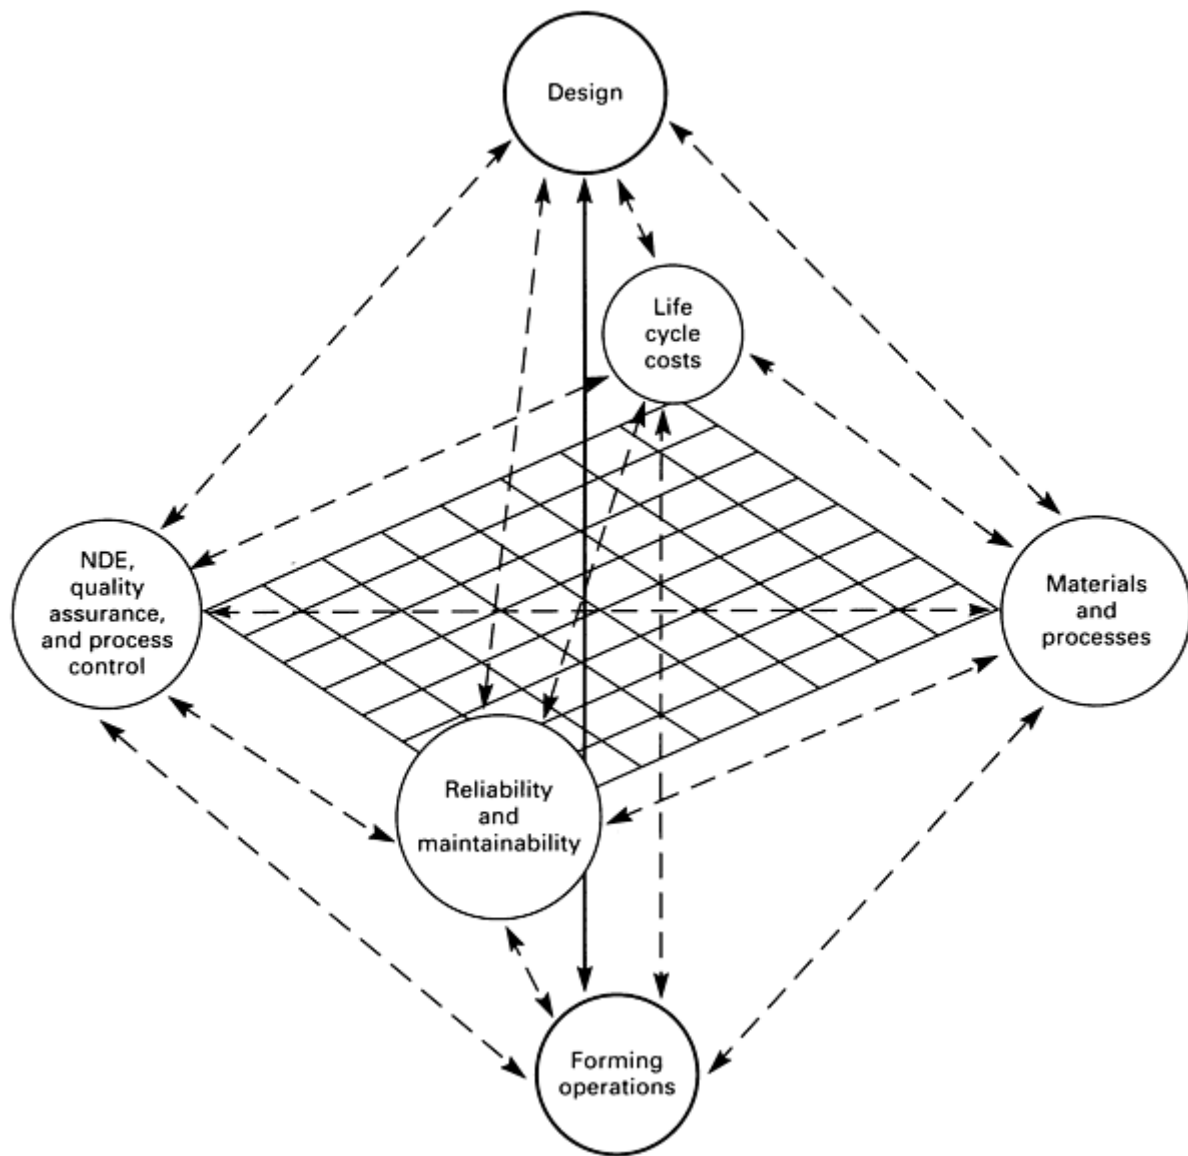

Fig. 3 Schematic of possible linkages needed for unified life cycle engineering

Given these objectives, it is obvious that an NDE model must exhibit certain characteristics. First, it must predict the response of a real measurement system, as influenced by the specific characteristics of commercially available probes and instruments, rather than an idealized response based on assumptions such as plane wave illumination. Second, the models should give as outputs the information obtained by real inspection protocols. For example, if a signal strength is compared to a threshold as a criterion for detection, this operation should be simulated by the model. If separate protocols are followed in detection and sizing, these should be described by separate models. Third, the models should be used to develop more reliable standardization approaches. This is necessary to ensure that inspections specified in the design process are uniformly implemented by NDE units at the various manufacturing and maintenance departments encountered by the component in its lifetime. Fourth, it is desirable in certain industries for the models to be configured such that they can be integrated with standard CAD packages. This article discusses some ultrasonic, eddy current, and x-ray radiography models that have been developed to exhibit the characteristics mentioned above. As noted previously, primary emphasis is placed on formulations that have been developed in response to the particular needs of the aerospace industry. This article also presents a broader discussion of possible future applications of a reliability modeling capability.

Ultrasonic Inspection Model

Empirical determinations of ultrasonic inspectability based on demonstration experiments are of limited utility because their predictions cannot, in general, be extrapolated to new situations beyond the bounds of the data set upon which they are based. Additional data are needed in order to apply them to other cases, and the costs and time required to develop such results for all (or many) possible component designs and scan plans are prohibitive. However, the physical principles upon which many different ultrasonic inspection techniques are based, as applied to a variety of components, are quite similar. Therefore, a mathematical model, whose validity has been proved against a relatively small amount of empirical data, can be used to accurately predict inspectability beyond the bounds of the experimental evidence.

The foundation of a physically based mathematical or computer model of ultrasonic inspectability is an analytical formalism, a numerical algorithm, or a combination of the two incorporating the physical principles of the measurement. Such a model consists of descriptions of the waves radiated by the probes, their modification by the geometry of the testpiece, the wave propagation and scattering from defects, and the effects of signal processing and display. The first four sections below review the technical details of each of these elements as developed to describe measurements made in aircraft engine components.

In the fifth section, the use of the models to predict the POD of flaws is discussed. The prediction of the POD for flaws is emphasized because of the importance of that parameter in damage-tolerant design. Other uses of models, such as assisting in the interpretation of data during flaw characterization and sizing, are also important but are not explicitly discussed. Some early applications of POD models are summarized in the sixth section.

Reciprocity Relation. The ultrasonic NDE simulation models described in this section are based on the formalism of the electromechanical reciprocity relationship of Auld (Ref 9). This relationship, when specialized to the case of elastic wave scattering, can be expressed as follows. Assume that two identical ultrasonic transducers, a and b, are placed in a fluid to be used in an immersion, pitch-catch measurement (a single probe, or pulse-echo, configuration is a special case) of a component containing a flaw, F. Let Γ be the ratio of the electrical signal radiated into coaxial line b by the receiving transducer to the electrical signal incident on the transmitting probe from coaxial line a. Then the change, $\delta\Gamma_F$, in this signal induced by the presence of the flaw in the insonified region of the component is given by:

$$\delta\Gamma_F = \frac{1}{4P} \int_{S_F} \left(\dot{\mathbf{u}}_b \cdot \boldsymbol{\sigma}_a - \dot{\mathbf{u}}_a \cdot \boldsymbol{\sigma}_b \right) \cdot \mathbf{n} d^2A \quad (\text{Eq 1})$$

where $\dot{\mathbf{u}}_a$ and $\boldsymbol{\sigma}_a$ are the displacement vector field and the stress tensor, respectively, that would be produced in the presence of the flaw when probe a is excited by an electrical power P , $\dot{\mathbf{u}}_b$ and $\boldsymbol{\sigma}_b$ are the fields that would have been established in the absence of the flaw if probe b had been excited, the overhead dot denotes time differentiation, S_F is an arbitrary closed surface enclosing the flaw, and \mathbf{n} is the inward normal to that surface. Equation 1 is an exact result known as the electromechanical reciprocity relationship. Its simplicity, however, belies its intractability, except in a very few special cases of limited practical use.

Measurement Model. A number of approximations and simplifications are necessary in deriving an accurate yet computationally efficient inspection measurement model from Eq 1. One situation for which a useful and accurate model can be extracted from Eq 1 through rather remarkable simplifications is the pulse-echo inspection of isotropic, homogeneous elastic materials containing small flaws of fairly simple shape. This is applicable, for example, to typical ultrasonic inspections of gas turbine aircraft engine components, in which fracture-critical flaws are quite small because of the high stresses created during engine operation.

The assumption of small in this case means that the dimensions of the defect are small relative to the variations in the transverse profile of the ultrasonic beam. The ultrasonic fields can be approximated locally as plane waves whose displacement and stress fields are the same as those of the true fields (Ref 10). Scattered fields can also be simply modeled, provided their variation is not significant over the face of the receiving transducer. These fields can be represented by the product of a spherically spreading wave times the far-field, unbounded medium scattering amplitude of the flaw (Ref 10). This scattering amplitude A is formally defined as:

$$u_s = u_0 A \frac{\exp(-ik_s r)}{r} \quad (\text{Eq 2})$$

where u_s is the displacement amplitude of the fields at a distance r from the center of the flaw, u_0 is the amplitude of an illuminating plane wave, and k_s is the wavenumber of the scattered wave mode. A time-harmonic term of the form $\exp(i\omega t)$ is implicitly assumed in this discussion. However, the model has the capacity to deal with pulses, as described later.

Applying these approximations to Eq 1, the a fields (those produced when probe a is fired and the flaw is present) are expressed as the sum of a plane wave illuminating field and a scattered field due to that plane wave, using the scattering amplitude as in Eq 2. The b field is simply a plane wave term representing illumination by probe b in the absence of the flaw. After some manipulation of the resulting integral and neglecting higher-order terms, a measurement model is derived that represents the measured signal as a product of factors describing the effects of transducer efficiency, transmission through interfaces, attenuation and beam spread, and scattering (Ref 10). Specifically, one finds:

$$\begin{aligned} \delta\Gamma_F = & \beta(T_a C_a)(T_b C_b) \frac{i2A\rho_1 V_b}{k_b a_T \rho_0 V_0} \\ & \times \exp\{-i[k_0(z_{oa} + z_{ob}) + k_a z_{1a} + k_b z_{1b}]\} \\ & \times \exp\{-[\alpha_0(z_{oa} + z_{ob}) + \alpha_a z_{1a} + \alpha_b z_{1b}]\} \end{aligned} \quad (\text{Eq 3})$$

where β is an efficiency factor; $T_a C_a$ and $T_b C_b$ represent local plane wave amplitudes at the flaw depth for the a and b fields (these are the product of interface transmission, T , and beam diffraction, C , factors); A is the scattering amplitude of the flaw; $\rho_1 V_b$ and $\rho_0 V_0$ are the acoustic impedances of the solid and fluid media, respectively; k_b is the wavenumber for the received wave mode; a_T is the transducer radius (which is assumed to be the same for both a and b); and the two exponential terms represent the ultrasonic phase change and attenuation, respectively. Equation 3 represents only one frequency. A frequency spectrum can be obtained via superposition of individual frequency terms. Thus, time-domain waveforms, such as would be observed on an oscilloscope screen, can be obtained by an inverse Fourier transform of this measurement model spectrum. (Further details of this derivation and the determination of the efficiency factor β in Eq 3 can be found in Ref 10.) Work at a number of institutions has led to formulas, algorithms, and data bases for the ultrasonic beam and scattering amplitude factors in Eq 3, so that a variety of useful simulations can be made, including

the use of planar or focused probes (Ref 11, 12, 13, and 14), inspection through planar or curved liquid/solid interfaces (Ref 11, 12, 14, and 15), and scattering from both volumetric (Ref 16, 17, 18) and cracklike (Ref 17, 19) defects. These aspects of the measurement model will be described in subsequent sections in this article. An alternative formulation, appropriate when the flaw is not small, is found in Ref 4.

As an example, Fig. 4 shows a comparison of an experimental pulse-echo radio-frequency (RF) waveform obtained from a circular flat crack versus two model-based simulations. The magnitude of the Fourier spectrum of each RF signal is also shown. The simulated crack was a circular, disk-shaped cavity 0.8 mm (0.032 in.) in diameter and 0.08 mm (0.003 in.) thick located in a diffusion bond plane of a specimen of a nickel-base powder metal alloy (IN 100). The specimen was a 25 mm (1.0 in.) thick plate. The face of the crack was parallel to the surface of the sample, and a 10-MHz, 6.35 mm (0.25 in.) diam unfocused transducer was tilted approximately 7° from normal to the sample surface to generate a 30° refracted longitudinal wave in the sample.

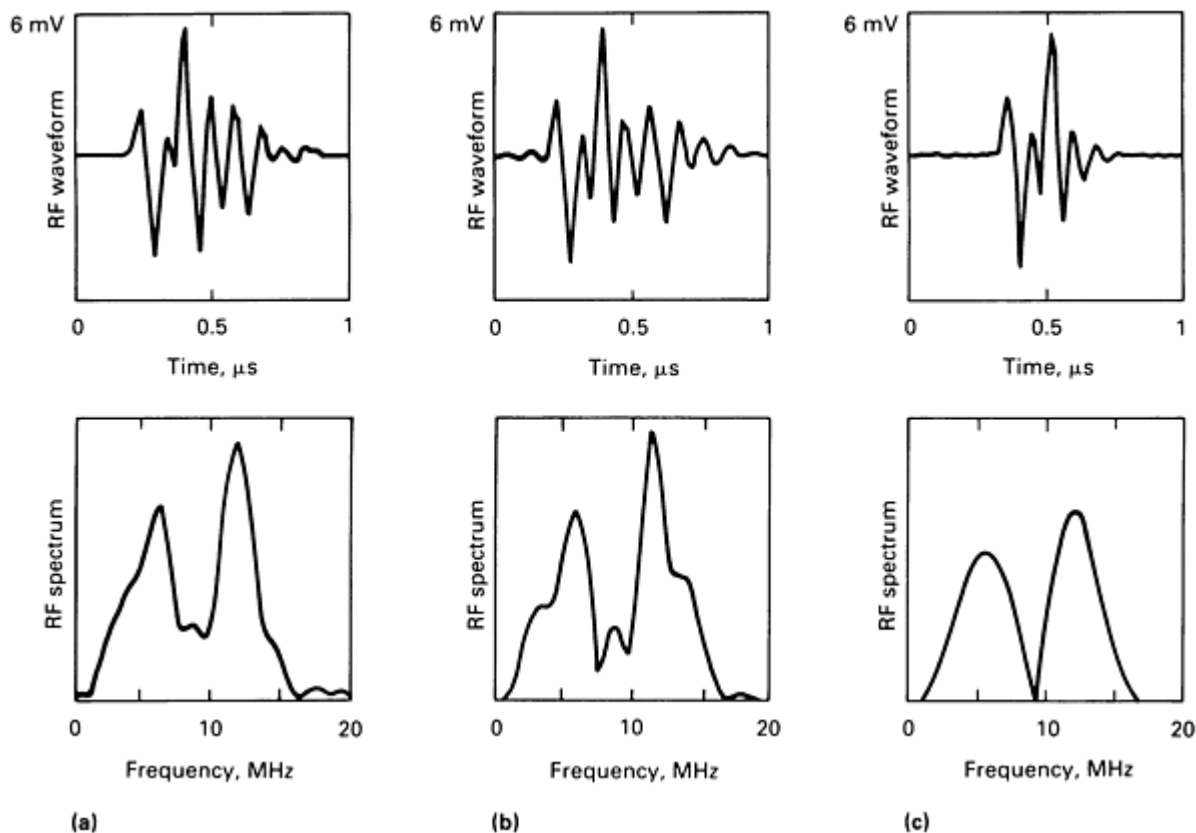

Fig. 4 Comparisons between experimental and model-predicted RF waveforms (top) and their Fourier spectra (bottom) for 30° longitudinal wave backscatter from a 0.8 mm (0.03 in.) diam circular crack in IN100. (a) Experimental measurements of scattering amplitudes (top) and their Fourier spectra (bottom). (b) Model of scattering with method of optimal truncation. (c) Model of scattering with the Kirchhoff approximation

The scattering amplitudes used in Fig. 4 were either results of the method of optimal truncation (MOOT) (Ref 17), which is a computationally intensive algorithm, or the elastodynamic Kirchhoff approximation (Ref 19). The experimental and MOOT results are very nearly identical in both the time and frequency domains. Because the MOOT results are in quasi-exact agreement with the measured scattering amplitudes in this case, this comparison highlights the accuracy of the measurement model. The Kirchhoff model result fails to reproduce some of the detailed wiggles of the experimental and MOOT results, but quite accurately reproduces the overall signal amplitude (voltage). This amplitude is the measured quantity that is routinely used in ultrasonic flaw detectors. Therefore, the approximation, which in this case yields a simple and computationally efficient model, can simulate a practical inspection problem. Note, however, that the error of the Kirchhoff model will depend on the flaw size and the orientation and polarization of the ultrasonic wave. Care must be taken to ensure that sufficient accuracy is obtained in particular applications by validating the model through comparison with controlled experiments and/or more exact theories for special cases.

Beam Models. To perform the preceding comparison, one essential element in the simulation was the representation of the ultrasonic fields in the vicinity of the flaw. Because of the finite size of any realistic transducer, these fields will be quite complex, exhibiting peaks and valleys along the axis of the beam and side-lobes away from the axis. The simulations shown in Fig. 4 represent the case of a scatterer on the axis of the beam, for which a number of approximate beam models have been generated (Ref 11, 13, 14). In a typical automated ultrasonic scan of a component, however, a defect in that component will not generally lie along the axis of the ultrasonic beam. The degree of misalignment will depend, for example, on the coarseness of the scan mesh used to inspect the part. To simulate such an inspection situation, it is necessary to incorporate the full fields of an ultrasonic transducer into the model. This is a formidable task because of the elastic (tensor) nature of wave propagation in a solid and because of the need to consider the interaction of the probing fields with a possibly curved liquid/solid interface at the component surface. However, two approximations have emerged as useful models of transducer radiation patterns: the Gaussian model (Ref 12) and the Gaussian-Hermite model (Ref 13, 14, 20).

The former, and simpler, of these models assumes that the transverse profile of the radiation profile is Gaussian in shape at all distances from the probe. This Gaussian beam model provides a set of simple algebraic formulas that predict diffraction effects (beam spread only), effects of lenses, and refraction/focusing due to transmission through curved liquid/solid interfaces (Ref 12). However, typical ultrasonic transducers do not generate Gaussian radiation patterns. For example, typical piston-type radiators exhibit side-lobes and peaks and nulls along the axis of the probe in the near field. However, in the far field (that is, several times the near-field distance), the Gaussian model, if suitably normalized, does accurately predict the amplitude and width of the main lobe in the radiation pattern of a typical piston-type transducer (Ref 12). One application of this approximation, therefore, is the simulation of the fields near a focal region, which can occur either as a result of an acoustic lens on the probe or the focusing effect of a curved component surface.

The Gaussian-Hermite model is based on a series expansion of the radiated fields of a transducer in terms of a complete set of orthogonal solutions to a reduced wave equation (Ref 13, 14, 20). These functions are products of a Gaussian factor and a Hermite polynomial. The coefficients in the series expansion are obtained by integrating the product of the Gaussian-Hermite functions and the velocity distribution on the face of a probe over its area. This distribution and the shape of the probe face are arbitrary, so that virtually any probe shape, lens type, and so on, can be modeled. The laws for transmission through curved liquid/solid interfaces and propagation in elastic isotropic media are implemented as simple algebraic operations. The primary disadvantage of the Gaussian-Hermite model is that it is a series solution and therefore can require significantly longer computation times than the Gaussian approximation because of the need for a large number of terms, especially in the near field. However, this becomes less of a disadvantage as computational speeds continue to increase as a result of advances in computer hardware.

Scattering Approximations. Another key element in the simulation of ultrasonic inspection of structures is the model, or models, for representing the interaction of the probing ultrasonic fields with defects. In the most general case, this is represented by a complicated and computationally intractable integral, such as Eq 1. In some cases, however, the effects of the probing ultrasonic fields can be separated from the scattering effects. Specifically, under the assumptions that led to the measurement model (Eq 3), the ultrasonic beam can be described by one of the models just mentioned. For example, elastic wave scattering can be modeled through the use of a far field, unbounded medium scattering amplitude, whose definition was given in Eq 2. Fortunately, considerable research effort has been directed over the past several years toward the development of various models, approximations, and solutions for scattering amplitudes of both volumetric and cracklike defects (Ref 3).

For application to the ultrasonic inspection of jet aircraft engine components, a reasonable inventory of scattering models includes formalisms for both volumetric and cracklike flaws. For volumetric flaws, of ellipsoidal shape and arbitrary orientation, both voids and inclusions can be represented by an elastodynamic Kirchhoff approximation (Ref 18). This approximation is exact in its treatment of the strength of the front surface reflection (δ function). It is valid for both longitudinal and shear wave backscatter, such as would be used to simulate pulse-echo inspections. The limitation of this model, however, is that it is accurate only for early-time events in the scattering. Therefore, it does not predict the amplitude of scattered fields that have reverberated within an inclusion; in some cases, these scattered fields can be of higher amplitude than the initial front surface reflection. The Kirchhoff approximation is therefore a conservative model for scattering from volumetric flaws. It does have the benefit of simplicity and computational efficiency.

For cracklike flaws, an elastodynamic Kirchhoff approximation to scattering from internal flat cracks of elliptical shape has been implemented for both pulse-echo and pitch-catch techniques and for longitudinal and shear wave modes (Ref 19). This Kirchhoff approximation accurately predicts the specular content (mirror reflection) of scattering, but does not properly include edge diffraction contributions or surface wave modes. It also does not contain any provision for surface roughness or partial closure of the crack faces. It does, however, yield reasonably accurate predictions of signal

amplitudes in the near-specular regime, as can be inferred from Fig. 4. One fairly significant limitation of the model is its inaccuracy in the nonspecular regime. It predicts, for example, that the scattering amplitude is identically zero for edge-on incidence from a crack, which is inconsistent with established crack scattering results (Ref 17, 21). However, the model is of significant utility because an inspection system for detecting cracks would be set up to take advantage of specular orientations, if possible. Furthermore, in this case, the Kirchhoff approximation is a simple and computationally fast algorithm.

Probability of Detection Models. One important application of ultrasonic measurement modeling is the simulation of probability of detection. Detection is appropriately described in terms of a probability for several reasons. A given size and type of defect may occur at random positions and with a range of orientations within each of a set of nominally identical components. The detailed shape of the defect may vary in a way that influences its ultrasonic response differently from its fracture response. Variations in grains, porosity, surface roughness, and so on, as well as the electronic equipment in a detection system, will cause noise, which will interfere with the signals from a flaw. Therefore, a given size and type of defect will exhibit a distribution of signal amplitudes if measured in a population of components containing such defects. Because these signal amplitudes are compared to a preset amplitude threshold in typical flaw detectors, some of the flaws will be missed, while others will be detected. The POD is the ratio of the number of flaws that are detected to the total number of flaws in the inspected components.

A formalism to predict the probability, $p(S, N, T)$, that a given signal, S (video envelope), in the presence of noise with total power N^2 will be detected by exceeding a threshold, T , is given by:

$$p(S, N, T) = \int_T^\infty \frac{r}{N} \exp \left[-\frac{(r - S)^2}{2N^2} \right] i_0 \left(\frac{rS}{N^2} \right) \frac{dr}{N} \quad (\text{Eq 4})$$

where $i_0(z) = \exp(-z)I_0(z)$, with $I_0(z)$ being the modified Bessel function of the first kind and order zero. This approach, based on work performed by Rice (Ref 22), was developed for a narrow-band signal, as is typical in radar analysis. Equation 4 represents only the probability of detecting a single signal level, S , and does not take into account the distribution of signal amplitudes for variations in the size, shape, and type of flaw.

A POD model for ultrasonics has been developed by using the measurement model to calculate the variability of signal levels as influenced by the position and orientation of the flaws. Then, for a given root-mean-square noise level, N , Eq 4 can be used to represent the probability that the video signal from a specific defect (a given size, shape, type, location, orientation, and so on) in a given component (material, geometry, and so on) and using a specific inspection system will exceed a threshold amplitude. As an example, let p_x and p_θ represent the probability distribution functions for the location, \mathbf{x} , and orientation, θ , of a given size, shape, and type of defect, and let $S(\mathbf{x}, \theta)$ represent its signal amplitude, as simulated by the measurement model. An expression for POD, assuming a noise level N and a detection threshold amplitude T , can then be written formally as:

$$\text{POD} = \int_\theta \int_{\mathbf{x}} p(S(\mathbf{x}, \theta), N, T) dp_x dp_\theta \quad (\text{Eq 5})$$

where the integrals are taken over the range of orientations and positions of possible flaws (Ref 15). Obvious generalizations of Eq 5 can treat the effects of flaw shape, type, and so on.

Equation 5 does not contain an explicit factor to represent the probability distribution of the presence of flaws; therefore, it predicts the probability that an ultrasonic indication (signal plus noise) will be detected assuming that a flaw is, in fact, present. The use of the POD model to analyze reliability issues, such as the probabilities of falsely accepting flawed components or of falsely rejecting good ones, would require the incorporation into the model of the probability distribution function for flaws as a function of defect size, location within the part, and so on. The result of Eq 5 would then need to be further integrated with respect to that probability distribution.

Applications. Figure 5 shows the results of simulating the detectability (POD) of circular cracks at three different depths below a cylindrical component surface and for two different scan plans (Ref 6). Figure 5(a) illustrates the use of

the POD model to quantify the detection capability of an NDE system. For the specific parameters in that simulation, cracks that are otherwise identical have significantly different detectability levels, depending on their depth below the surface of the part. In this example, the curved surface of the component behaves like an acoustic lens that happens to focus the beam at the middle depth (25 mm, or 1 in.). Because of the relatively coarse scan mesh and the reduced beam width in this focal region, there is a significant likelihood that a flaw will be located in a low-amplitude portion of the beam profile and, therefore not be detected. For the other two depths, the beam width is greater than the scan mesh distance. The plot in Fig. 5(b) shows the result of sufficiently refining the scan mesh so that the beam width at the focal region is greater than the distance between scan points. In this case, the POD curves are nearly the same for the three different depths. This example illustrates the use of the POD model for quantifying the capability of a flaw detection system and for suggesting improvements in this area in the system or its operation.

Fig. 5 Predicted influence of scan plan on POD. (a) POD at three depths for axial and circumferential scan increments of 2.5 mm (0.1 in.). (b) POD at three depths for axial and circumferential scan increments of 5 and 1.3 mm (0.2 and 0.05 in.), respectively

Another example of the use of the POD model is shown in Fig. 6 (Ref 6). The POD curve is expressed in a rather nonstandard manner, because it does not represent the typical POD versus flaw size plot. Instead, Fig. 6 shows the variation in POD due to modification of a geometrical parameter of a component. Specifically, the component is a simulated turbine disk assumed to contain radially oriented circular cracks below a bicylindrical fillet. The abscissa of Fig. 6 is the in-plane radius of curvature of that fillet. The flaw size is assumed to be constant, representing, for example, the critical flaw size as predicted by fracture mechanics. Most important, Fig. 6 shows that flaw detectability can be improved by modifying the geometry of the component. This information is important for the definition of sonic near-net shapes of components in production, for example, and ensuring in-service inspectability during maintenance. Moreover, because the characteristics of the inspection system are contained explicitly in the POD model, the scan plan required to achieve the necessary detectability levels are easily determined. This concept of predicting component inspectability at the design stage, of determining the component design parameters that favorably influence flaw detectability, and of incorporating the requisite scan procedure into the design data base is perhaps the ultimate application of inspectability modeling.

Fig. 6 Simulated POD for a 0.8 mm (0.03 in.) diam circular crack below a bicylindrical fillet as a function of fillet radius of curvature

Models for Predicting NDE Reliability

J.N. Gray, T.A. Gray, N. Nakagawa, and R.B. Thompson, Center for NDE, Iowa State University

Eddy Current Inspection Model

The eddy current NDE method has a long history of use (Ref 23, 24, 25, 26, 27, 28, 29, 30, 31, 32, 33, and 34). Because of its conceptually straightforward design principle, the method allows measurements to be made in a noncontacting, single-sided inspection geometry. Eddy current is therefore a cost-effective and truly nondestructive method of inspection. However, as a fully quantitative method, eddy current inspection has not achieved the level of sophistication found in other methods, such as ultrasonics and x-ray radiography. The reason for the delay in its development is associated with the fundamental nature of the measurement. In essence, the measurement response is a complex function of the probe fields and their interaction with the flaw, and it is difficult to isolate these two contributions. Therefore, one cannot develop simple models in which various effects can be described by separate factors, as in the case of ultrasonics. A significant problem has also been obtaining material property data (such as permeability and conductivity) for complex engineering materials. Welds are especially difficult.

From a modeling perspective, it is necessary to obtain electromagnetic field solutions for a given probe/flaw system by solving Maxwell's equations. When written in the form suitable to eddy current problems, the equations show that the basic dynamics are of a dissipative, nonscattering nature. One well-known consequence is that only near-surface flaws, confined within a region of a finite skin depth, are detectable. Putting this obvious limitation aside, there is a subtler problem posed by the basic principle. Namely, electromagnetic fields spread over a wide region outside the specimen, permitting no simple way of focusing the probe sensitivity to flaw regions. (In the other inspection methods, the beam focusing, for example, can be used for this purpose). The impedance signal, being an integrated quantity, contains not only flaw information but also redundant environment information (such as probe lift-off), which is uninteresting in terms of flaw detection and characterization and may contribute significant noise. Extracting flaw information from impedance signals therefore becomes highly dependent on component geometry and is a computationally intensive task.

Many efforts have been devoted to overcoming this difficulty, and the results have been promising (Ref 25, 26, 27, 28, 29, 30, 31, and 32). Rapid progress has occurred recently in computational methods with regard to both hardware and software. It appears that the new-generation desktop workstations are sufficiently capable of handling the computational requirements of eddy current data analyses. One may find an even better situation when using eddy current models to

assist in design processes, for which state-of-the-art supercomputers may be available. In addition to progress in hardware, researchers are applying certain new software techniques to eddy current problems. With new software running on powerful computers, the difficulty in numerical analyses is becoming obsolete. Recent experimental advances have also proved beneficial. Emphasis is placed, more than before, on making characterizable probes and on operating them in broad frequency ranges. In fact, no fully quantitative eddy current methods can be established without these two capabilities. Incidentally, all existing eddy current POD models discussed in the literature rely on some type of experimental input for noise characterizations (Ref 30, 34).

Reciprocity Relation. On the theoretical side, the appearance of a reciprocity formula, proposed by B.A. Auld (Ref 31), has been regarded as a breakthrough in that it provides a formalism for interpreting measurements in realistic experimental geometries. The formula gives the impedance change ΔZ due to the presence of a flaw in the form:

$$\Delta Z = \frac{1}{I^2} \oint (\mathbf{E}' \times \mathbf{H} - \mathbf{E} \times \mathbf{H}') \cdot \mathbf{n} dS \quad (\text{Eq 6})$$

where \mathbf{E} and \mathbf{H} denote electric and magnetic fields in the absence of the flaw, and \mathbf{E}' and \mathbf{H}' denote the fields in the presence of the flaw. The integration in Eq 6 is carried out over a surface enclosing the flaw, with \mathbf{n} being the inner-directed surface normal. The attractive feature of Eq 6 is that flaw signals can be evaluated as soon as electromagnetic fields are obtained in the vicinity of a flaw region. Equation 6 has been proved effective in impedance evaluations and has been used in many applications. Auld's theory, which was built around a combination of the reciprocity relation and the Born approximation, has been playing a central role in the existing eddy current POD studies.

A word of caution is necessary concerning the reciprocity formula. Although its use is highly recommended, the reciprocity formula is not the ultimate method for conducting impedance evaluations. In fact, the most versatile method is the direct use of Faraday's law, which works under any circumstances. However, this method usually results in the most computationally intensive efforts. A third possibility is to use the energy conservation law. This method, however, is the least versatile because it is not always possible to estimate an amount of energy escaping from the system. There are no general criteria for method selection. A case-by-case comparison is required, taking cost-effectiveness and the required degree of accuracy into account.

Probe-Flaw Interaction Models. To make the eddy current method quantitative, one must be able to predict flaw signals for any given system. Earlier, equivalent circuit methods were attempted (Ref 23). The present consensus is that detailed evaluations of electromagnetic fields are needed to make sufficiently precise predictions.

One therefore needs to solve Maxwell's equations, assuming that all the system parameters (that is, a probe, a part, a flaw, and the inspection geometry) are given. Such mathematical techniques as exact methods, integral equation methods, perturbation theory, and variational methods are frequently used. Various approximation schemes can also be employed. In the literature, the integral equation methods are used most frequently, where the basic differential equations are cast into integral equations using appropriate boundary conditions. Particularly popular are the three-dimensional finite-element method and the boundary integral equation (BIE) method.

Again, selection of the most suitable method for a given situation should be done on a case-by-case basis. The three-dimensional finite-element method is the most versatile, but is also the most expensive. For crack problems, the BIE method may be favored in several aspects. Typically, an eddy current system is piece-wise homogeneous, consisting of several spatial regions separated by sharp boundaries. Moreover, the boundaries are rigid surfaces that are not subject to change over time. Clearly, this is an ideal situation for applying the BIE method. Another favorable aspect is that the aforementioned reciprocity formula uses only field values on boundaries. As long as it is applicable, the BIE approach gives a faster algorithm than the three-dimensional finite-element method. There are, however, situations in which the BIE method fails to work well. For example, it is not effective when dealing with flaws caused by corrosion where conductivity may vary continuously in space. Presumably, this type of flaw is still confined in a local region. If so, it is possible to solve the problem with a combination of the BIE and three-dimensional finite-element methods. To the best of the authors' knowledge, such a combined approach has never appeared in the literature. Perturbation theory may be useful if the variation is small. The perturbation method should certainly be used more frequently in dealing, for example, with a conductivity fluctuation, which is an important noise source to consider in POD models.

Probability of Detection Models. In this section, definitions of probability of detection and probability of false alarm (POFA) will be given in a form suitable for the eddy current inspection method. Various, inequivalent definitions are seen in the literature, but the intention here is to illustrate the basic idea.

Suppose that an eddy current inspection system is specified and that a series of impedance measurements is carried out over a flaw at a given frequency. By nature, the measured signals will scatter around a mean value in a complex impedance plane. Distribution A shown in Fig. 7 illustrates a typical data distribution from a flawed area, while distribution B represents a data set taken under the same controlled conditions but over an unflawed part. Strictly speaking, a flaw signal is given by the difference between the on-flaw and off-flaw signals; the flaw signal corresponds graphically to the shift of the two peak positions, A and B. The fluctuations around the peaks reflect the noise characteristics of the given inspection system.

Fig. 7 Illustration of signal distributions. Measured impedance values will follow a certain distribution. Distribution A illustrates an on-flaw signal distribution (signals measured on a flaw), while B illustrates an off-flaw signal distribution.

Once signal/noise distributions are given, one can begin to study the inspectability of the system, as follows. Consider a window in the impedance plane (for example, C in Fig. 8), and make a hypothesis that any signal falling in this window is actually a flaw signal. Then, POD is defined by the probability of this hypothesis being true, which is equal to the integral of distribution A over window C (provided the total integral of A is normalized to unity). Similarly, POFA is given by the integral of B over C, that is, the probability of off-flaw signals being mistaken as flaw signals. The POD and POFA

values thus evaluated are functions of C , and when evaluated for various windows, they will form a domain in a POD-POFA plane. Such POD-POFA plots can be used as a measure of inspectability. Alternatively, representatives of POD and POFA values can be used for specification, such as those in which the maximum POD/POFA ratio is achieved.

Fig. 8 The same distributions as in Fig. 7 viewed from above. Window C will be used to define POD and POFA as integrals of the distributions over C.

Therefore, the fundamental task is to determine the on-flaw and off-flaw signal distributions for a given system. One important theoretical task, for example, is to predict the peak positions A and B with model calculations. Noise distributions are more difficult to predict because, by nature, any measurement system will contain certain unpredictable noise sources. Nonetheless, to make eddy current POD packages an effective design aid, as much effort as possible should be devoted to the complete identification and characterization of conceivable noise sources. References 30 and 34 contain specific examples of POD calculations, and Fig. 9 illustrates an example of a POD-POFA plot.

Fig. 9 Sample plot of POD-POFA curves for different flaw sizes. Source: Ref 12

Discussions and Future Directions. Comparing the goal just stated with the current developmental status in the literature (Ref 30, 34) will lead one to expect improvements in eddy current POD models in the following areas. First, theoretical models of limited capabilities have been used for impedance calculations. These limitations inevitably restrict the applicability of the existing POD models. For example, the models have been probe specific, limited to work only for certain measurement geometries, and so on. Any progress in forward calculations will provide more flexible POD models.

Second, noise characterizations have been accomplished almost exclusively by relying on experimental input. In view of using POD models as a design aid, this is not an ideal situation, because one needs to build a prototype system before calculating POD. Unfortunately, this trend will continue until sufficient data have been accumulated so that reliable general formulas can be extracted empirically. Very little has been done to find purely theoretical noise simulations.

Finally, as a part of software development, a program shell of a POD package should be established, following the general guideline of POD evaluations. Ideally, the package will be written based on a modular programming concept. It may consist of three basic modules: impedance calculation, noise calibration, and POD calculation. Once the shell is written, any progress in either forward calculation or noise characterization can be implemented quickly into the package by replacing the appropriate modules.

There are also two technical recommendations. First, although POD itself can be calculated for a fixed frequency, it is of crucial importance to enable the system to handle a broad range of frequencies. Without this capability, no precise determinations of flaw sizes and shapes can be expected. This applies equally to hardware and software developments. Second, few of the previous measurement techniques and associated POD models fully exploit the complex nature of impedance. Both the real and imaginary parts should be treated on an equal footing as described above in order to make full use of valuable information.

It should be emphasized that, so far, the concept of inspectability has been defined for systems as a whole, so that one can discuss the POD of a system but not the POD of a single component. To validate the notion of the POD of a given probe, it is necessary to integrate the probe into an inspection system in which all the other system components are strictly controlled to meet certain specifications. In the future, such a standardization may become an important issue for comparison purposes.

Models for Predicting NDE Reliability

J.N. Gray, T.A. Gray, N. Nakagawa, and R.B. Thompson, Center for NDE, Iowa State University

Radiographic Inspection Model

In radiographic modeling, one is essentially trying to predict how the two-dimensional projection of an irregularly shaped object changes as the position of the object changes with respect to the x-ray beam and detector and, further, to study the degree to which various parameters control image quality (Ref 35, 36). The requirements for a quantitative model of the radiographic process consist of the ability to predict the output of an x-ray generator, the interaction of the x-ray beam with the sample, and the detector characteristics. The capability to handle complex part geometries and non-trivial flaw morphologies is required if the simulation is to have wide application.

Gray *et al.* have developed a full three-dimensional radiography model that generates a two-dimensional (x,y) film image (Ref 37, 38) rather than the one-dimensional source-sample-detector dimension previously modeled (Ref 39). The full

shadowing effects and the radial divergence of the x-ray beam in the projections are included, allowing a realistic treatment of complex part geometries. The model consists of:

$$I(x,y,E) = I_0(E) \int_{\text{source}} \frac{e^{-\mu(x,y,E)\rho(x,y)}}{r^2(x,y)} dA \quad (\text{Eq 7})$$

$$D(x,y,E) = D_0(1 - e^{-\sigma[(1+\eta)I(x,y,E)t+\delta]}) \quad (\text{Eq 8})$$

In Eq 7, E is the energy, I is the intensity immediately above an xy point on the detector, I_0 is the initial intensity produced from the x-ray generator, μ is the energy-dependent linear absorption coefficient, ρ is the x-ray path length through the sample, and r is the distance from the source to the detector.

In Eq 8, D is the film density, σ is the interaction cross section of an x-ray with a film grain, η is the coefficient for the x-ray scattering, t is the time of the film exposure, δ is the natural film fog density, and D_0 is the maximum film density. The integration goes over the area of the source, thus including the affect of source properties on image quality. This model of the x-ray radiographic process has the capability of modeling a very large number of parameters that affect the image quality of an x-ray radiograph. As noted in Eq 7 and 8, the major elements of the model include an x-ray beam model (I_0), the interaction of the beam with a nontrivial sample, and a detector model. These must be combined with a detectability criterion in order to complete a POD prediction.

Beam Model. The model of the initial x-ray beam involves a first-principles prediction of the energy-dependent x-ray intensity spectrum calculated from the bremsstrahlung and characteristic interaction cross sections (Ref 40). These cross sections are calculated from the interaction of the relativistic electron beam with the bound atomic electrons of the target atom and are based on a one-photon production process. The angular dependence of the bremsstrahlung cross section is integrated over all angles. This simplification implies that the calculated intensities will require a scaling factor to match the experimentally measured values. The energy dependence of the spectrum is calculated assuming a thick target attenuation of the electron beam. This beam model has features that allow variation in the beam focal-spot size, shape, and uniformity. Further, the target material and angle of incidence to the electron beam are variables. The model accounts for the inherent filtration of the generated x-ray beam by the target material and the vacuum window of the exit port. Features that the beam model does not address are the generation of off-axis x-rays, the interaction cross sections that involve the generation of more than one photon, the physical mechanics of electron beam focusing, and the variation of the voltage from power supply. These features influence the intensity of the beam and at present are handled in the beam model with an intensity scaling factor.

Sample Interaction Model. The interaction of the x-ray beam with the sample monitors the energy-dependent attenuation through the sample (Ref 41). This portion of the model includes the effects of the sample shape, the flaw morphology, and the configuration of the experimental setup. The sample shape currently used in the simulation is a flat plate with surface roughness. The simple part shape allows the effects of many parameters to be isolated from those involving the complex part shapes.

Two types of flaws are available for study in the simulation. The first is an ellipsoid with nine independent parameters characterizing its shape, orientation, and position. The position of the origin, the three major axes, and three Euler angles give complete, arbitrary control of the position and shape of the ellipsoid. The ellipsoid can be a void or an inclusion. Further, the sample position relative to the source or detector, the thickness, and the material can be chosen as desired, thus providing a wide range of setup geometries. The second flaw is a truncated cone whose apex angle, truncation distance, composition material, and xyz position in the sample can all be varied. Additional features are the ability to model density variations in the material and a wide choice of sample materials ranging from low atomic number carbon-base materials to high atomic number materials such as tantalum. As noted above, the sample shape is limited. However, future integration of the simulation into a CAD package will remedy the lack of a wide variety of shapes because any part geometry that the CAD package can generate can be used in the simulation. A note on the introduction of complex CAD-generated part shapes is that the calculation of the POD can take significant amounts of time, at least with present computer capabilities.

Detector Model. If film is used as the detector, a model of the film simulates a number of film speeds, maximum densities, and the energy-dependent effects of the x-ray interaction with the silver halide grains. The film model is derived by considering the number of grains that have absorbed x-ray photons, which absorb an additional photon as a result of the flux incident on the film. The number of photons required for a silver halide grain to be developed is energy

dependent. For very low energy (10 keV), several photons are required, while at high energy (1 MeV), one photon can activate several grains. Unfortunately, the energy dependence of grain activation is also dependent on the likelihood of x-ray absorption, a feature that is dependent on the size of the grain and the energy of the x-ray photon. These energy-dependent features are reflected in the x-ray interaction cross section, σ . This cross section, together with the grain size, gives the film model the capability to model the speed of the film (Ref 42). The total amount of silver halide grain present, as represented by the weight of the emulsion, controls the maximum film density, D_0 . The fog density, δ , of the unexposed film can be accounted for in the final density.

The film model tracks the random counting statistics noise and in a limited set of sample geometries tracks the noise due to Compton scattering. For simple geometries, the Compton scattering is a uniform intensity at the film and is modeled through the scattering coefficient, η . This is a simplistic approximation to a complex problem. Indeed, the Compton scattering for energies above several hundred kiloelectron volts is the dominant scattering mechanism and can contribute more to the film density than the information-carrying portion of the beam. The additional complexities of part geometry nullify the uniformity of the Compton scattering at the detector plane, making a detailed tracking of the Compton component necessary. The addition of this important effect is the subject of ongoing research.

Detectability. The detectability criterion accounts for the physiological limitation of the human eye to detect, under normal conditions, variations in gray film scale levels. The determination of the limits of gray-scale variation that the human eye can perceive is based on studies of uniform gray background with a circle that has a different gray-scale level (Ref 35). Although this is not the general condition under which radiographs are viewed, this is the criterion currently incorporated into the model. Further modification involves a mechanism to account for degradation of the contrast due to a poor signal-to-noise ratio. One of the features of the simulation is the capability of turning off the noise, thus allowing examination of the noise degradation of the signal. The noise in the film image is, in most cases, dominated by the random fluctuations of the number of photons impinging on a unit area. The result is that the noise magnitude is related to the density of the film; higher noise is associated with low densities, while low noise corresponds to high density. This has led to the incorporation of contrast degradation due to noise and therefore to the inclusion of its influence on flaw signal detectability. This detectability model falls into the amplitude model class of detectability, and although a simple model, it has the major features for adequately describing detectability (Ref 43).

Limitations. At present, there are a number of limitations to the model. They include a limited accounting for the effect of Compton scattering, the need for an intensity scaling factor for the initial beam, and a simple detectability model. Experimental verification of the major components is under way, and the preliminary results are very good. The initial beam model gives results that only need scaling to accurately model the observed x-ray spectrum. The film model can characterize the film response to a photon flux for a wide range of film types. For the full simulation, with only the scaling for the initial beam intensity, the results, when compared to an actual radiograph of a machined cone-shaped void, are in the worst case within a factor or two of the actual film densities. In the best cases, the model results are within 20% of the observed results. The refinement of the model is work that is ongoing.

Applications. With this highly flexible model of the radiographic process, several factors affecting flaw detectability can be studied in a quantitative manner. A sample of the types of effects studied can be seen in Fig. 10 and 11, in which the loss of detectability was simulated for changes in beam hardness and flaw orientation, respectively. The simulation predicts a range of kilovoltages for which adequate contrast and noise levels are present. To perform adequate x-ray inspections, the data must be collected in these plateau regions. It should be noted that the sizes of these optimal regions are also strongly controlled by the flaw shape and size. The loss of detectability was calculated quantitatively based on the physiological limitation of human vision to discern variations in gray shades, the noise level present in the radiograph, and the contrast available.

Fig. 10 Simulation results showing the effects on thickness sensitivity of the x-ray beam hardness and the relative size of the flaw to sample thickness

Fig. 11 Detectability of different ellipsoidal flaws as a function of their orientation and shape. The shape of the ellipsoid is changed by varying the aspect ratio, where two of the major axes are kept equal and the third is decreased. The ratio of the constant major axes to the smaller is the aspect ratio. As the aspect ratio increases, the ellipsoid flattens and becomes cracklike. The scale for angular orientation is chosen such that a crack is optimally oriented at 90°.

Figure 10 shows a plot of the effect of beam hardness (the white spectrums of a harder beam have a higher average energy) on the detectability of a flaw where the film type, the sample composition, the x-ray beam shape, and the physical geometric setup were kept the same. The time of the exposure was increased to attain the same film densities for each simulated exposure. As can be seen, the harder beam has less sensitivity but a shorter exposure time, while the softer beam yields greater sensitivity at the cost of longer exposure times. Thus, the trade-off between sensitivity and speed of inspection can be studied.

Figure 11 shows the effect of flaw morphology on detectability. The flaws represented in Fig. 11 have widely varying aspect ratios, thus simulating varying degrees of crack tightness. As the orientation of these cracks with respect to the incident x-ray beam changes, their detectable signal drops abruptly.

There are a number of applications of the forward model of the x-ray radiographic process in the field of production inspection. The first is the collapsing of the full three-dimensional aspect of the model to a one-dimensional line path. This allows quick calculation of the kilovoltage, current, and time required for the exposure of a type of film to the density required. Another is in the area of inspection validation studies. The use of seeded defects and image quality indicators and the sensitivity testing of various parameters are time consuming and expensive, so much so that a full study in which all parameters are varied is rarely done. The use of a simulation program coupled with a set of benchmark trials can greatly expand the scope of this type of certification of an inspection procedure. Modest extensions of the model would facilitate an even wider range of applications. The prediction of a full POD requires only the addition of a probability distribution function describing the flaw distribution, as described in the section "Ultrasonic Inspection Model" in this article. As can be seen from Fig. 10 and 11, the current model is very close to the generation of POD curves for different system parameters. A second area for extension is the simulation of tomographic scans. The addition

of a detector model typical of those used in tomographic scans will allow the generation of the projection data required for the reconstruction algorithms.

Models for Predicting NDE Reliability

J.N. Gray, T.A. Gray, N. Nakagawa, and R.B. Thompson, Center for NDE, Iowa State University

Future Impact of Models

The three preceding sections describe computer models that can be used to generate quantitative predictions of inspectability for ultrasonic, eddy current, and x-ray film methods. These are all physically based models that explicitly consider the characteristics of the realistic flaws, the typical component geometries and materials, and the practical inspection methods and practices. These or similar models may:

- Replace costly and time-consuming experimental demonstration programs in the prediction of NDE reliability
- Improve the validation and optimization of inspection procedures
- Improve component design and the definition of the life cycles

Another potential application of NDE reliability models may involve integration with CAD systems. This approach could allow the assessment of inspectability during the design stage just as form, fit, and function are analyzed during design. The integration of NDE reliability models with a CAD system may also allow quantitative estimates of inspection reliability as a function of design changes. The following example, illustrated in Fig. 12 and 13, describes this application of NDE/CAD integration for ultrasonic inspectability (Ref 8). The inspectability (POD) model for ultrasonic NDE has achieved the highest state of technical maturity, and initial strides have been made toward its incorporation into CAD systems. However, the general idea is applicable to NDE reliability models of inspection methods other than ultrasonics.

Fig. 12 Example of a CAD-generated display of inspectability (POD) as a function of position within the cross section of a simulated disk. The POD scale ranges from black for the lowest to white for the highest POD values. The low POD in the fillet region is due to the combination of a coarse scan mesh and a tight fillet radius.

Fig. 13 A display similar to the one shown in Fig. 12, except that the scan mesh has been refined and the fillet has a larger radius of curvature. The combination of scan plan and component design modification has significantly improved inspectability throughout the disk.

Example 1: Integration of an Ultrasonic Reliability Model with a CAD System.

Figures 12 and 13 show the result of a computer simulation of ultrasonic POD for oblate spheroidal inclusions in a rotationally symmetric component, such as a jet engine turbine disk. The display shows the results obtained from a cross section of the component, and the gray shades refer to the POD value, in the range from zero to unity, with black being the lowest and white the highest POD values. In the POD simulation, the inclusions were assumed to have a preferential orientation with their largest face parallel to the component surface, and the component was assumed to be scanned in pulse-echo mode with a focused probe normal to the surface of the part and focused at the surface. The interior points of the component, at which the POD values were calculated, were defined to be the nodes of an automatically generated finite-element mesh that was imposed on the solid model of the part. This artifice allowed the built-in postprocessing graphical interface of the CAD package to be used to display the inspectability results in a format that would be very familiar to a designer who is experienced in the use of the package.

Figure 12 shows the result of a nominal scan plan and component design. In particular, the scan mesh was quite coarse, causing poor detectability in the web section to the right of the cross section and near the surface of the entire component. The fillet region, at the juncture between the web and the thicker bore area to the left of the cross section, was also assumed to have a small radius of curvature. Below this fillet region, the POD values are quite low, which is a result of the combination of the ultrasonic beam being focused on the surface of the part and of the focusing effect of the surface curvature. This caused the fields in the region below the fillet to be rapidly diverging and therefore of low amplitude.

To improve the POD levels throughout the component, two questions must be considered. The first is whether the inspection technique was optimized with respect to the design of the component, and the second is whether the design itself is inspection limited. The first question is crucial because a simple modification of the scan plan will almost certainly be a better solution than the change in operational characteristics of the component created by a modification of its design. In some cases, however, both the scan plan and the design will require optimization. Figure 13 shows the result

of both options; the scan mesh was refined, which caused the enhanced POD in the near-surface and web regions, and the fillet radius of curvature was increased, which improved the POD in the fillet region.

Example 2: Implications on Standardization.

As the design applications of reliability models become more widespread, the questions of quantitative standards will become more important. Because the manufacturer will usually be at a remote location from the designer and may be affiliated with a different organization, it will be necessary to communicate the inspection procedure at the time that manufacturing procedures are specified. Absolute calibration standards will then be essential to ensure that the inspection, including specified thresholds, is properly set up and implemented. This may require a move away from the use of reference reflectors, such as flat-bottom holes (Ref 44, 45). Recent work in ultrasonics has shown how the measurement model, Eq 3, can be used as the basis for such a procedure (Ref 46).

Example 3: Uses of Artificial Intelligence in Optimization.

An important part of the consideration of inspectability in CAD procedures is optimization of the inspection and/or design. This was done intuitively by a highly trained operator in Example 1. However, in the future, it may be desirable to eliminate the operator through the use of artificial intelligence techniques, such as expert systems. Although this has not yet been accomplished, a step in that direction has been the use of the ultrasonic measurement model in the development of an expert system to differentiate cracklike flaws from volumetric flaws (Ref 47).

Introduction

A MAJOR REVOLUTION in the industrial sector has been taking place in America during the 1980s as manufacturers strive to regain the competitive position they once held in the world marketplace. One element of this revolution has centered around a renewed emphasis on quality, with an approach aimed at preventing defective materials from being manufactured through improved process monitoring and diagnosis and at designing quality into the product from the very beginning. The concepts and methods of Deming and others have had a profound impact on the way quality is viewed from the manufacturing/process perspective. The simple but powerful statistical methods for process control developed by Shewhart some time ago have been successfully revived and applied on a very broad basis. In the engineering design arena, the methods of Taguchi, referred to as off-line quality control, have been successfully used for more than 30 years to provide a sound basis for improved product/process design. From the total system point of view, the concept of company-wide quality control, which has been practiced in Japan for some time, is now receiving considerable attention. In particular, recent emphasis has been placed on quality function deployment as a means to transmit customer needs through the organization both vertically and horizontally.

The work of Shewhart in the 1920s led to a sound approach to the scrutiny of process variation and the diagnosis and removal of process faults. However, the statistical approach to the sampling of process output prior to shipping to determine the extent to which it conformed to specifications dominated the quality field from the 1930s through the 1970s. Unfortunately, it has only recently been recognized that this product control approach to quality control contributes little to the enhancement of competitive position. The recognition that quality and productivity can move together in the right direction only when the process is evaluated, finding the root cause of process faults and taking action to remove them, is today reshaping the meaning and intent of quality control.

The dramatic change in the meaning and application of quality control as a discipline has both a philosophical and an analytical side. These two aspects of the problem must be understood together. This article will present some fundamental elements of statistical thinking and methods for quality design and control. Commonly used techniques employing control charts and the design of experiments are discussed with illustrations.

Quality and Productivity Fundamentals

Dr. W. Edwards Deming is the man largely responsible for bringing statistical thinking and methods for quality improvement to Japan after World War II. An eminent statistician in America during the 1930s and 1940s, Deming was one of the men in the forefront of the statistical quality control scene during World War II. After the war, Deming's philosophies and teachings fell on the deaf ears of American management, and the quality effort fires that burned so brightly during the war years slowly went out. However, the Japanese became aware of Deming's work and invited him to Japan, where he met with and caught the attention of top management.

When Deming first traveled to Japan in the late 1940s, he found a climate that was quite conducive to the promotion of his concepts and methods. On the one hand, Japan appeared to have a solid base of statistical expertise, although its energies had been directed primarily toward mathematical theory and the application of that theory in nonmanufacturing

environments such as agriculture. On the other hand, Deming found an industrial leadership base in Japan very eager to listen to what he had to say. With the lessons learned from his experience in attempting to promote quality improvement in America, Deming's first order of business when he arrived in Japan was to conduct a series of top management training seminars in which he laid out what needed to be done to place quality improvement on an institutional basis within any organization. The obligations and responsibilities of management that he spelled out in these seminars came to be known as his Fourteen Points for management.

Perhaps it is the combination of upper management perspective and a firmly rooted background in mathematical statistics that has enabled Deming to sustain his efforts in a leadership position over more than 50 years. He has been able to tell management what they ought to do and then to provide the rigorous analytical tools and methods needed to carry out his directions. His teachings are heavily oriented toward the use of statistical thinking and methods to identify opportunities for quality and productivity improvement. Deming has developed a road map for management to follow to enhance competitive position over the long run. This road map, referred to as his Fourteen Points (management's obligations), is summarized below. It should be noted that in the spirit of his Fourteen Points, Deming continues to this day to refine and improve these tenets. As a result they themselves are continually changing. An excellent discussion of Deming's Fourteen Points is provided in Ref 1. Deming's Fourteen Points are listed below:

- Create constancy of purpose for the improvement of product or service
- Adopt the new philosophy of process control and variation reduction
- Cease dependence on mass inspection for quality control
- End the practice of awarding business on the basis of price
- Improve constantly and forever the system of production and service in order to improve quality and productivity and thus continuously decrease costs
- Institute thorough and better job-related trainings
- Institutionalize leaderships
- Drive out fears, so that everyone may work effectively for the company
- Break down barriers between departments
- Eliminate slogans, exhortations, and targets for the workforce that ask for zero defects and new levels of productivity
- Eliminate work standards on the factory floor
- Remove the barriers that rob employees at all levels in the company of their right to pride of workmanship
- Institute a vigorous program of education and self-improvement
- Put everybody in the organization to work to accomplish the transformation

The Fourteen Points are clearly the responsibility of management. They define the essential elements of the institutionalization of quality and productivity improvement through statistical thinking and methods. Other pioneers in quality planning and management include Dr. J.M. Juran (Ref 2) and Dr. A.V. Feigenbaum (Ref 3).

Quality and Engineering Specifications

In today's economic age, it is simply impractical to use concepts and measures of quality that do not relate the achievement of function in the field to the engineering design process. Definitions of quality that promote improvement to some acceptable plateau of performance will inhibit the continual pursuit of never-ending improvement and will therefore have a weak and perhaps opposing relationship to process performance in terms of efficiency/productivity. Instead, to improve competitive position, the definition of quality should emphasize:

- A design criterion to provide a quantitative basis to move the quality issue upstream to engineering design
- Prevention rather than containment to promote focus on the process, not the product, in a manufacturing sense
- Continual pursuit of never-ending improvement to be strongly tied to, and therefore promote, the issue of productivity
- Consumer versus producer orientation to quantify/measure the loss imparted to the customer as a result

of poor quality rather than the loss imparted to the producer

The traditional definitions of quality often fall short in terms of their ability to articulate quality in a way that can foster improvement in competitive position. In particular, the association of quality with conformance to the engineering specification puts the measurement of quality on an attribute basis and provides little more than a shipping criterion when it is essential that quality be articulated in a manner that enables it to be used as a design criterion. The view of quality as conformance to specifications promotes the product control approach to quality control and therefore stands as a significant inhibitor to the adoption of a process control approach to manufacturing and the integration of quality and the design process.

Figure 1 illustrates the traditional interpretation of the engineering specification. Figure 1(a) and 1(b), two representations of a process as a statistical distribution of measurements are shown relative to a certain bilateral specification. Although the bell-shaped process distribution in Fig. 1(a) might be preferred to the more loaf-shaped process distribution in Fig. 1(b), there generally would not be much distinction between the two cases in terms of quality; that is, in both cases, virtually all the processes/parts are conforming to the specifications.

Fig. 1 Graphical depiction of three traditional interpretations of engineering specifications. (a) Desirable. (b) Acceptable. (c) Nominal

When one begins to consider the dots labeled A, B, and C as representing three different manufactured parts in Fig. 1(c), part A is generally interpreted as unacceptable because it is outside the specifications, while parts B and C are considered acceptable because they are within the specifications. The crucial point in this interpretation is the fact that a distinction is generally not made between parts B and C so far as quality is concerned. In fact, it is unlikely that there is very much difference between parts A and B in terms of functional performance, while part C will likely perform considerably better than either A or B.

Loss Function Concept

The methods of Taguchi have provided a whole new perspective on the way the engineering design process is viewed and have provided further support to the methods of design of experiments for quality design and improvement (Ref 4, 5). The design of experiments as a discipline has a rich and extensive history that finds its origin in the work of Sir Ronald Fisher during the first quarter of the 20th century (Ref 6). From an industrial point of view, the work of Dr. G.E.P. Box and his coworkers has left an indelible mark on the design of experiments in particular and the theory and practice of industrial statistics in general (Ref 7, 8).

The Taguchi approach to quality engineering has a number of significant strengths. In particular, Taguchi has placed a great deal of emphasis on the importance of minimizing variation as the primary means of improving quality. The concepts of designing products such that the performance of each is insensitive to environmental conditions and making this happen at the design stage through the use of design of experiments have been cornerstones of the Taguchi methodology for quality engineering.

Taguchi suggests that it is important to think of quality in terms of the loss imparted to society during product use as a result of functional variation and harmful effects. Harmful effects refer to the side effects that are realized during the use of the product and are unrelated to product function. Functional variation refers specifically to the deviation of product performance from that intended by design, that is, from the nominal. Specific sources of functional variation will be discussed later in this article. Taguchi uses a loss function concept to quantify quality as loss due to functional variation. Figure 2 illustrates the idea of the loss function.

Fig. 2 Plot of quality loss versus quality characteristic to illustrate concept of loss function of quality

The loss function concept as a way to measure quality clearly suggests that the goal of design and manufacturing is to develop products and processes that perform on target with smallest variation. It places tremendous importance on the reduction of variation to achieve the most consistently performing products and processes. To drive performance toward this overall objective, more must be learned about the way in which the important parameters of the product/process influence performance. Over the years, the methods of design of experiments have been proved to be an effective way to do this.

Figure 3 provides an interpretation of the loss function concept when overlaid on the traditional engineering specification definition of quality. In this way, no loss would be considered as long as the quality characteristic in question lies within the lower and upper specification. Outside of the specifications, the product is considered to be unacceptable, and a constant loss would therefore be realized. This loss would likely be measured in terms of scrap cost or rework cost. The following case study suggests that this interpretation is illogical.

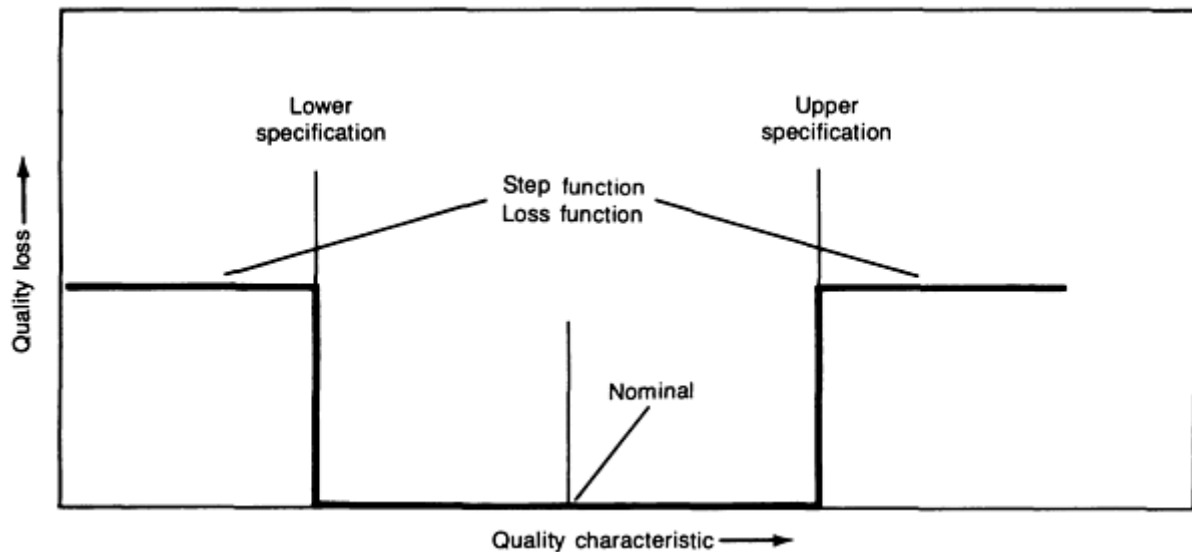

Fig. 3 Plot of quality loss versus quality characteristic to illustrate loss function of engineering specification

Variation Reduction and the Loss Function. The loss function view of quality suggests that there exists a clear economic advantage to reducing variation in the performance of a product. The case study described below clearly indicates how such reduced manufacturing imperfection can lead to a reduction in costs and therefore an improvement in competitive position.

Several years ago an automobile company performed a study to compare the manufacturing variations evident in certain transmission components for comparable transmissions made in the United States and in Japan. Random samples of transmissions were selected in each case. The transmissions were disassembled, and a number of critical dimensions were measured and recorded.

Figure 4 illustrates the general findings of the study. In particular, in the case of the U.S. transmissions, the critical dimensions generally consumed about the middle 75% of the tolerance range specified. Normally, one would conclude that the capabilities associated with the manufacturing processes are therefore well within normal expectations. However, the same critical dimensions for the Japanese counterpart of this transmission consumed only about the middle 25% of the same tolerance range. The question that begs to be asked is, Why would the Japanese strive to make the parts to such tight tolerances?

Fig. 4 Comparison of critical dimensions for transmission components manufactured in the United States versus

those manufactured in Japan

The warranty cost bars shown in Fig. 5 have been plotted at the extremes of the two distributions of the critical dimensions to depict the relative costs associated with variability. It is clear that for the U.S. transmissions the cost associated with repair and replacement is significantly larger than that for their Japanese counterparts. This comparison of the economic data associated with the two transmissions would suggest that there exists a definite relationship between variability and cost in terms of loss incurred due to functional variation. One could think of the warranty costs as literally mapping out the loss function.

Fig. 5 Loss function interpretation of the engineering specifications in Fig. 4 in terms of warranty costs

Robust Design Approach to Quality Design

The design process in general and the design/manufacturing interface in particular have received considerable attention over the past 20 years. Computer-aided design and manufacture has dealt primarily with the computerization of the design and manufacturing processes and in particular with the translation of design specifications into manufacturing procedures and activities. The computer has greatly facilitated this translation, and as a result, lead times have been reduced. Design modeling and analysis have been strengthened and extended. Standardization and rationalization of both design characteristics and manufacturing process characteristics have been advanced, and the efficiency of the interactive process at the design/manufacturing interface has been improved.

The concepts of design for manufacturability and design for assembly have been the subject of considerable research and development. Numerous specific models have been proposed and refined and will not be discussed here. This work is aimed at overcoming the difficulties precipitated by the traditional over-the-wall design philosophy.

The magnitude of the problem with the over-the-wall approach to design and manufacturing can perhaps be measured in terms of the number of times the part drawing is thrown back and forth over the wall. As the initial design concept progresses from prototype testing and development to final design detailing and ultimately to the initiation of production and beyond, the number of design interactions has in the past been too high. In Ref 9, typical Japanese and U.S. companies are contrasted in this regard with an illustration similar to Fig. 6.

Fig. 6 Comparison of Japanese and American product design life cycles

Taguchi methods have strong engineering orientation and focus primary attention on the engineering design process, particularly the projection of a three-stage design process model of system design, parameter design, and tolerance design. Figure 7 illustrates the Taguchi design process model (Ref 4, 5).

Fig. 7 Block diagram illustrating Taguchi's three-stage design process model

Systems Design Stage. In the initial stage, systems design (the available science, technology, and experience bases) is used to develop and select the basic design alternative to meet customer needs. A variety of techniques may be useful in specifically mapping the relationship between customer needs and the selection of design configuration and parameters that will effectively meet those needs. The methods of quality function deployment may be most useful at this stage of the design process.

At the parameter design stage, interest focuses on the selection of the specific nominal values for the important design parameters. The overarching selection criterion is to identify those nominal values that minimize the transmission of functional variation to the output performance as a result of the presence of noise factors. It is at the parameter design stage that Taguchi strongly advocates the use of design of experiments methods.

The tolerance design stage of the design process concentrates on the selection of allowable tolerances for the important design parameters. The loss function concept of quality is used to provide a basis for striking the proper economic balance in the selection of design.

Product/Process Performance Factors. Taguchi suggests an engineering interpretation of the varying roles that the important system factors/variables play in influencing product/process performance. Taguchi emphasizes the importance of evaluating quality performance as part of the design process. Taguchi classifies the factors that can influence product/process performance into four categories:

- *Signal factors:* Factors that can be adjusted by the user to attain the target performance. Steering angle, for example, is a signal factor for the steering mechanism of an automobile
- *Control factors:* Product/process design parameters whose values are to be determined during the design process. One design activity is to select the optimum levels of the control factors according to an appropriate design criterion
- *Noise factors:* Factors that are either inherently uncontrollable or impractical to control because of technological/economic reasons. Taguchi further classifies these into outer and inner noises
- *Scaling/leveling factors:* Special cases of control factors. They are factors that can be easily adjusted to achieve a desired functional relationship between a signal factor and the output response. For example, the gearing ratio in a steering mechanism can be easily adjusted to achieve a desired relationship between the turning radius and the steering angle

Signal factors are those variables adjusted to attain the target/nominal performance. The control factors are those variables under the control of the designer. Selection of the nominal values for the control factors is the primary role of parameter design. Noise factors describe those variables that are difficult or impossible to control but whose variation is analyzed to understand the way it is transmitted to the output quality. To minimize the effects of outer and inner noises on product quality, certain countermeasures can be taken. The most important of these countermeasures is that of design. A product is said to be robust if its design is such that its performance is minimally influenced by uncontrollable noise factors.

An automobile design can be said to be robust if, for example, the fuel economy remains fairly constant over a wide range of speeds, road conditions, and wind velocities. This is shown graphically in Fig. 8.

Fig. 8 Effect of three noise factors on automotive fuel efficiency (mpg) to demonstrate a robust product (Car A). Car A offers peak performance over a wide range of conditions for all three factors, while Car B offers peak

performance over a limited range of conditions for each individual factor.

Sources of Variation and Their Countermeasures

To reduce functional variation, that is, to increase the consistency of product/process performance, it is essential to identify the basic sources of functional variation so that appropriate countermeasures can be formulated and implemented. Taguchi suggests that variations in product or process function (also known as functional variations) arise from three basic sources (Ref 4):

- *Outer noise*: External sources or factors that are operating in the environment in which the product is functioning and whose variation is transmitted through the design to the output performance of the product. Examples of outer noise factors are temperature, humidity, contaminants, voltage fluctuations, vibrations from nearby equipment, and variations in human performance
- *Inner noise*: Internal change in product characteristics such as drift from the nominal over time due to deterioration. Inner noise can be precipitated by such factors as mechanical wear and aging
- *Variational noise*: Variation in the product parameters from one unit to another as a result of the manufacturing process. For example, the design nominal for a resistor may be 200 Ω ; however, one manufactured resistor may have a resistance of 202 Ω , while another may have a resistance of 197 Ω

The significance of the recognition of the above sources of variation becomes evident as one begins to think in terms of the fundamental countermeasures one might invoke to mitigate the forces of these sources of variation. It quickly becomes clear that the forces of outer noise and inner noise can only be effectively dealt with upstream by the engineering design process. Variational noise is a matter of manufacturing imperfection and can therefore be dealt with, in part, at the process with such techniques as statistical process control. However, mitigating the forces of variational noise should also be considered to be a product and process design issue. In fact, it is likely that variational noise can be dealt with in a more significant and fundamental way if it is thought of as a process and product design problem. Certainly the concept of design for manufacturability and the current emphasis on the simultaneous engineering of products and processes have bearing on this issue.

Figure 9 illustrates how the sources of variation defined above are transmitted to the quality response of the product. At the product design stage, the nominal values of the critical design parameters are selected to produce a prespecified level of performance in the product in terms of one or more quality responses. Sources of variation active in the manufacturing processes for the product cause the design parameters to vary from those values intended by the design process, and this introduces variation into the quality response. Once the product is put into field use, outer noise sources of variation active in the environment in which the product is being asked to function are transmitted through the design and introduce further variation in the quality response. For example, variation in temperature may cause product performance to vary. As time goes by and the use of the product continues, the forces of inner noise are transmitted through the design and introduce still further variation into the quality response. For example, as a result of wear, a critical design parameter (size, resistance, viscosity, and so on) will actually change, thus causing a change in quality performance. From Fig. 9 it is clear that sources of variation enter the picture and affect the ultimate performance of the product during manufacturing and field use.

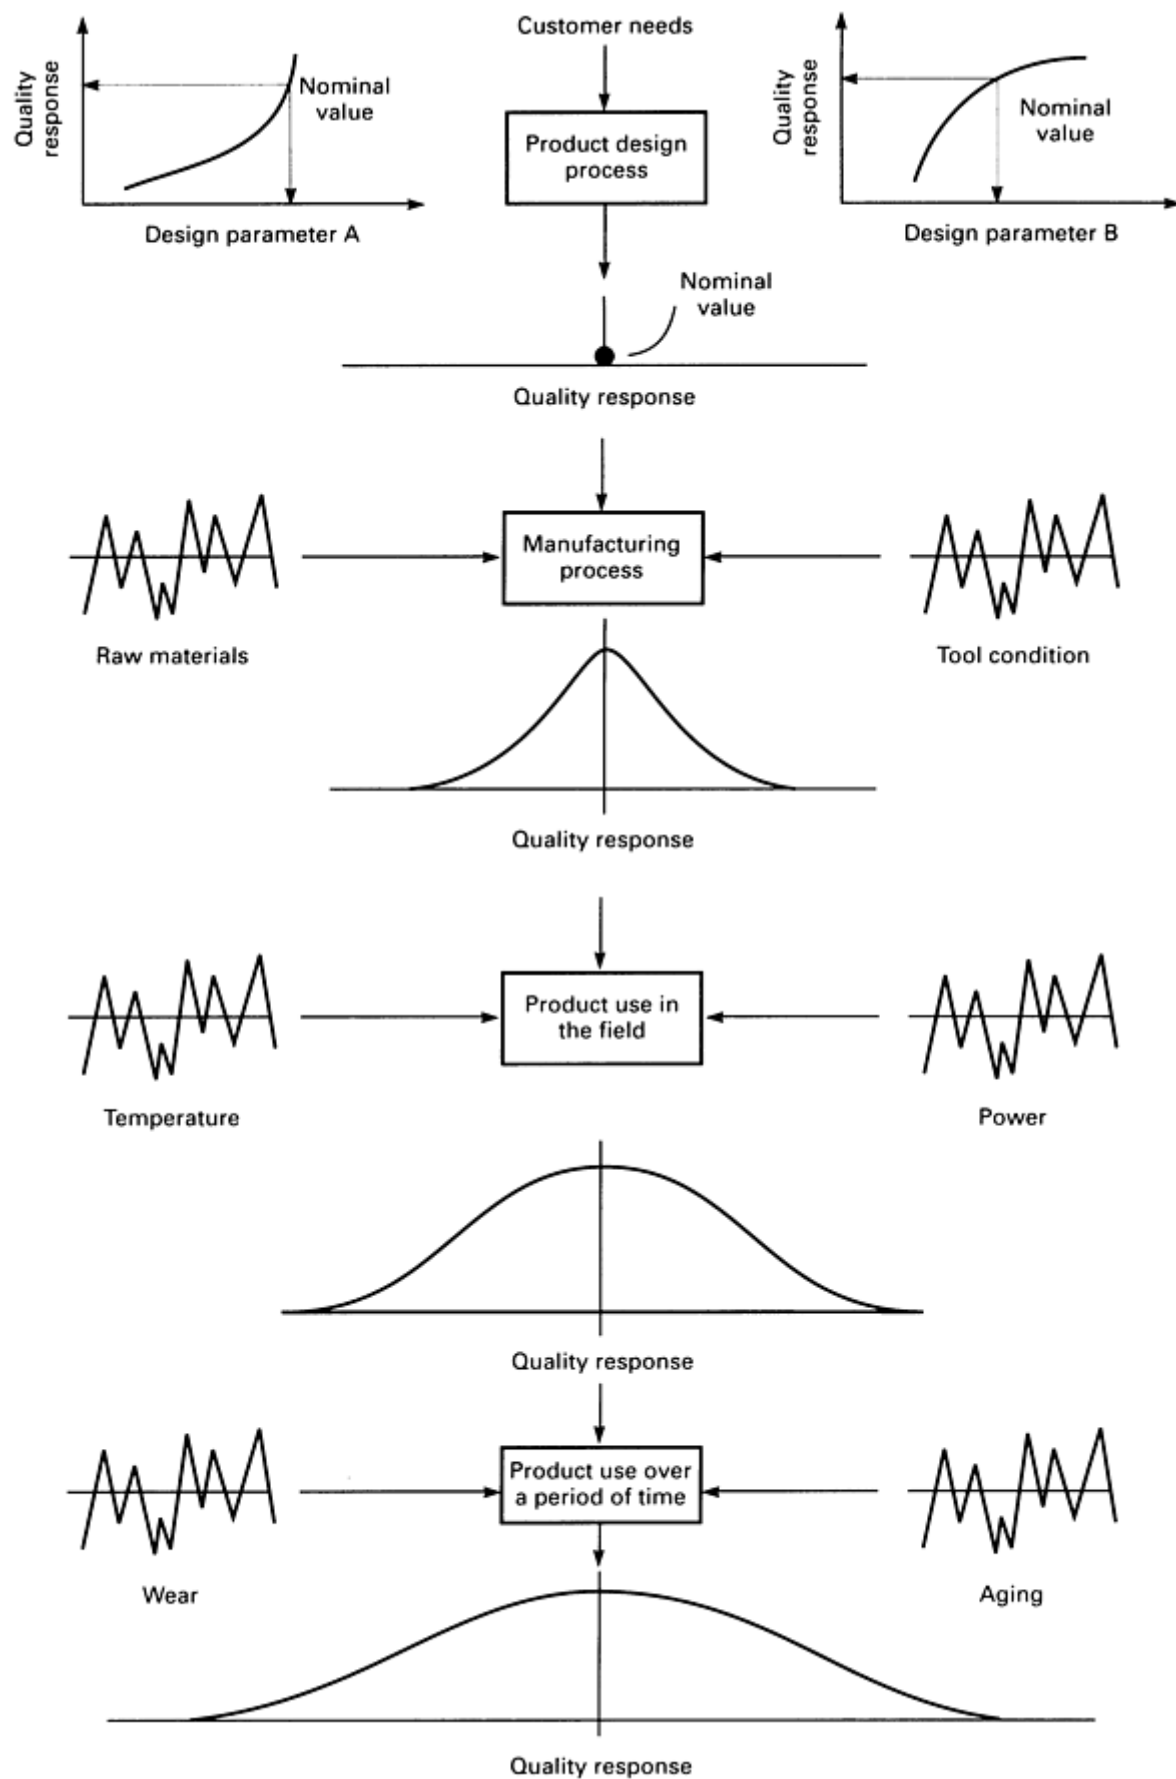

Fig. 9 Block diagram illustrating the impact of numerous sources of variation on the quality performance of a product from conception to eventual discard

Shewhart (Ref 10), Deming (Ref 11), and Juran (Ref 12) all clearly point out that quality and productivity problems at the process fall into two basic categories. Shewhart described the variation in the process as arising from either chance causes or assignable causes. Deming refers to systems faults and local faults, while Juran refers to chronic problems and sporadic problems. Each provides a lucid description of the overall situation. Assignable causes, local faults, or sporadic problems arise in a somewhat unpredictable fashion and can usually be dealt with effectively at the workstation by the immediate level of supervision or the operator. On the other hand, system faults/chance causes/chronic problems are ever present, influencing all of the production until the system is changed. It is the attack on the system problems that Deming stresses, because about 80 to 85% of all the problems encountered are of this nature, while only 15 to 20% are of a local nature.

All processes are subject to local faults and system faults:

Local faults Special causes Sporadic problems	System faults Common causes Chronic problems
Broken tools	Poor supervision
Jammed machine	Poor training
Material contamination	Inappropriate methods
Machine setting drift	Poor workstation design
Correctable locally, at the machine, by the operator or first level of supervision	Requires a change in the system; only management can implement changes

In the case of common causes, it is clear by their very nature that management must take the responsibility for their removal. Only management can take the actions necessary to improve the training and supervision of the workers, only management can take the responsibility for the redesign of a poor workstation layout, and only management can establish new methods or procedures. Clearly, it is essential that these two types of problems be properly differentiated so that responsibility can be assigned for solving them.

Process Behavior Over Time

A succession of parts emanating from a process under statistical control will exhibit variability in their measurements because of a constant set of common causes. These variable measurements tend to collect into a predictable pattern of variation that can be easily described by a few simple statistical measures; namely, a mean, a standard deviation, and a frequency distribution. These measures stand as a model that predicts how the process will behave if subject only to a constant set of common causes. Figure 10 illustrates how such a statistical model may emerge in the manufacture of automobile head gaskets. The gasket thickness (Fig. 10a) is the quality characteristic of interest.

Fig. 10 Schematic and statistical analysis of an automobile head gasket to demonstrate variability of the manufacturing process. (a) Gasket thickness specification. (b) Gasket thickness measurements taken of samples produced at 1-h intervals. (c) Histogram of mean gasket thickness. (d) Plot showing standard deviation of gasket thickness. (e) Plot showing distribution of gasket thickness measurements

Measurements of thickness can be recorded for a succession of gaskets produced by the process (Fig. 10b), and these data can be summarized by statistical measures, such as an average (Fig. 10c), a standard deviation (Fig. 10d), and a distribution (Fig. 10e). If a model can be developed for the process measurements when subject only to a constant system of common causes, then when a major disturbance affects the process measurement it will be seen not to conform to this model. It will clearly stand out in the common cause variability pattern.

Time Order of Production. Although the above statistical description and the interpretation of data are useful, they ignore a crucial characteristic of the data: the time order of production. To properly indicate statistical control or lack of it, the model must be considered as it evolves over time of production. Figure 11 shows the time order evolution of the process. In Fig. 11(a), the process mean and variation stay constant over time, and the process is said to be in statistical control. In Fig. 11(b), a process mean shift occurs at 11:30 a.m. The process is said to have gone out of control. A process can be subject to several types of disturbances (special causes) that can produce a variety of unstable behaviors with respect to either its mean level or the level of variability or both.

Fig. 11 Changing process behavior over a 5-h time interval. (a) Process in statistical control. (b) Stable variability but out-of-control process due to sustained shift in process mean at 11:30 a.m.

Process Control and Process Improvement

Many years ago, Dr. Walter Shewhart showed how such data from a manufacturing process could be developed and interpreted through the use of very simple but profound statistical methods. In his benchmark book on the subject, *Economic Control of Quality of Manufactured Product*, Shewhart establishes from the very beginning the overarching philosophy that drives the control chart concept (Ref 10). The first paragraph of the Preface of this work clearly sets the foundation for what is known today as statistical control:

"Broadly speaking, the object of industry is to set up economic ways and means of satisfying human wants and in so doing to reduce everything possible to routines requiring a minimum amount of human effort. Through the use of the scientific method, extended to take account of modern statistical concepts, it has been found possible to set up limits within which the results of routine efforts must lie if they are to be economical. Deviations in the results of a routine process outside such limits indicate that the routine has broken down and will no longer be economical until the cause of trouble is removed" (Ref 10).

From the above statement, several factors become immediately obvious:

- The fundamental focus is on the process--"ways and means of satisfying human wants"
- The overarching objective is economic operation of the process--"reduce everything possible to routines requiring a minimum amount of human effort"
- During normal operation, process behavior falls within predictable limits of variation--"It has been found possible to set up limits within which the results of routine efforts must lie if they are to be economical"
- Deviations in performance outside these limits signal the presence of problems that are jeopardizing the economic success of the process--"Deviations in the results of a routine process outside such limits indicate that the routine has broken down and will no longer be economical"
- Improvement in quality and productivity requires that attention be directed at the process to find the root cause of the trouble and remove it--"the routine has broken down and will no longer be economical until the cause of trouble is removed"

In addition, there is no mention of the product and the conformance of the product to specifications in the above statement from Shewhart. The total emphasis is on the process and its economic operation.

Bringing a process into a state of statistical control does not necessarily mean that a fundamental improvement has been achieved. Clearly, a bad situation has been rectified by bringing the process into control, and quality and productivity are enhanced. However, bringing a process into control simply means that the process is back to where it should have been to begin with. At this point, it is then possible to begin to assess the present ability of the process to realize the potential it was initially intended to have. It may be failing to realize this potential because the implementation of the process is flawed or because the design of the process itself is flawed. In either case, the root cause(s) of the chronic common cause problem must be identified and removed at the system level. This constitutes a breakthrough in performance; that is, an improvement in the process has taken place. The results of the essential steps leading to such a breakthrough are shown in Fig. 12.

Fig. 12 Impact of having process initially in a state of statistical control versus improvement resulting from a breakthrough in performance

Fundamental Purposes of Shewhart Control Charts

There are two fundamental purposes that Shewhart control charts can serve:

- As a tool to provide a sound economic basis for making a decision at the machine regarding whether to look for trouble, adjust the process, or leave the process alone
- As a means of assisting in the identification of both improvement opportunities through the detection of sporadic and chronic faults in the process and to help provide the basis to formulate corrective and improvement actions

Although these two purposes may appear to be essentially the same, they are not. The former is strictly an on-line activity, while the latter is an off-line activity. On line, the operator can only recognize and take action against the presence of special causes of variation. If the process, as monitored on line, is free of special causes, the operator is doing the best that he can. In short, if the process is in statistical control, the operator should do nothing at all to disturb the routine behavior of the process.

On the other hand, the fact that the process is in statistical control in no way guarantees that it is a capable process (able to meet customer expectations as they may be communicated through a specification). However, the operator cannot be expected to be responsible for this, though he may have some valuable insight into the problem. A lack of process capability is basically a product/process design and planning problem.

For the techniques of statistical process control (specifically Shewhart control charts) to be successfully employed as an off-line problem identification and problem-solving tool, it is essential to keep in mind that it is a three-step process, as follows:

- Use statistical signals to find improvement opportunities through the identification of process faults
- Use experience, technical expertise, and fault diagnosis methods to find the root cause of the fault that has been identified
- Develop an action plan to correct the fault in a manner that will enable any gains that are realized to be

held

This three-step process can be explained by using the classical feedback control system perspective, as shown in Fig. 13. There are five distinct stages in the generic control loop shown in Fig. 13. These five stages facilitate the three-step process in the following way:

- *Step 1:* Use of statistical signals (observation and evaluation)
- *Step 2:* Fault diagnosis (diagnosis)
- *Step 3:* Action plan (decision and implementation)

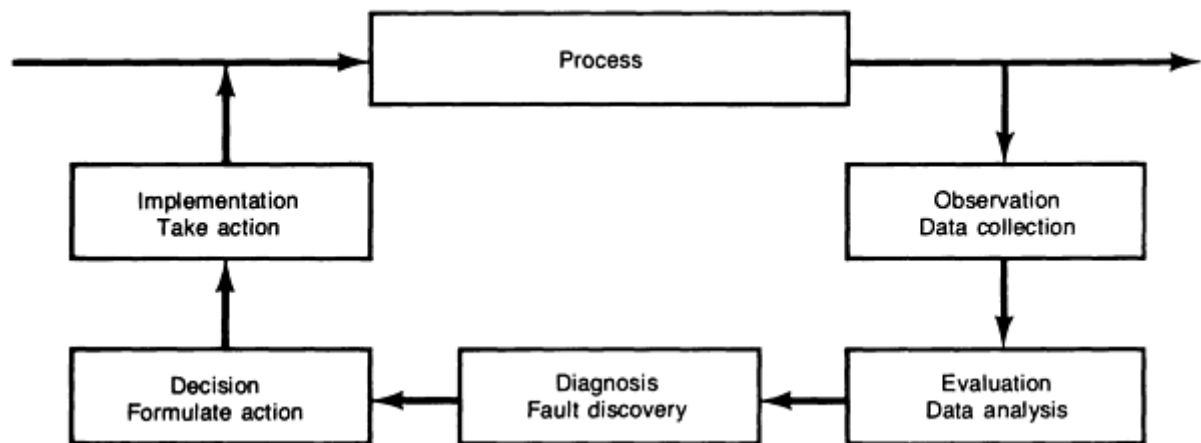

Fig. 13 Classical feedback control system view of statistical process control implementation

Construction and Interpretation of \bar{x} and R Control Charts

This section focuses on the construction and interpretation of Shewhart control charts for variable data, in particular, \bar{x} and R control charts. All the necessary equations and procedures for the calculation and graphical representation of the basic elements of the charts are presented. In addition, this section presents some probabilistic rules to aid in the interpretation of these charts.

Shewhart Control Chart Model

The control chart stands much as a jury in a court of law. The information from each sample is judged in order to determine whether or not it indicates the presence of a special cause disturbance. Unless the evidence is overwhelmingly in favor of the occurrence of a special cause disturbance, a verdict of not guilty is entered. In other words, there is no strong reason to believe that forces other than those of common causes are at work. Such an interpretation is, in fact, based on and consistent with the hypothesis-testing approach to making statistical inferences about the population/process based on information contained in the sample.

If a process under surveillance by periodic sampling maintains a state of good statistical control, this means that its mean level and level of variability remain constant over time. If such is the case, the sample means would have a distribution that follows the normal distribution, and nearly all the sample means would fall within the band of plus or minus three standard deviations of $\bar{\bar{x}}$, or $\pm 3\sigma_{\bar{x}}$, where $\sigma_{\bar{x}}$ is the standard deviation of \bar{x} about the established process average. Because the chance of realizing a point outside the $3\sigma_{\bar{x}}$ limits is so small if good statistical control is evident, the occurrence of such a sample result must be interpreted as signaling some special/sporadic departure from expected behavior; that is, something other than common cause variation must be present. Figure 14 illustrates the presence of such a special cause. The $3\sigma_{\bar{x}}$ limits about the process average/centerline are referred to as the upper control limit (UCL) and the lower control limit (LCL).

Fig. 14 Use of probabilistic limits to identify unusual process behavior over a period of time

Suppose a sample mean, \bar{x} , falls above the upper control limit. Because the chance of this occurring is so small (about $\frac{1}{8}$ of 1%) if the process mean is truly at the centerline, it must be assumed that some special cause is present that shifted the process mean to a different level. Unfortunately, the fact that all points fall within the $3\sigma_{\bar{x}}$ limits does not mean that special causes are not present. Departures from expected process behavior may not always manifest themselves on the control chart immediately or for that matter at all. Although narrower limits (for example, $2\sigma_{\bar{x}}$ limits) would allow easier and faster detection of special causes, such limits would also increase the chances of false alarms, that is, times when the process is actually in good statistical control but a sample mean, \bar{x} , falls outside the control limits.

Appropriate placement of the upper and lower control limits is an economic issue. The intent would be to fix the limits in such a way as to balance the economic consequences of failing to detect a special cause when it does occur and wrongly identifying the presence of a special cause when it has really not occurred. Experience has led to the use of $3\sigma_{\bar{x}}$ limits as a good balance of these risks.

Generally, chaotic disturbances manifest themselves in two possible ways:

- Shifts or changes in the mean level of the process
- Shifts or changes in the amount of process variability

Figure 14 represents only one side of the coin; thus, a fundamental rule has been violated--that an \bar{x} -chart should not be shown without the associated range chart. By monitoring the process through sampling, the sample mean, \bar{x} , can be used

to aid in determining when a change in the mean level has occurred. By determining the range, R , for each sample and tracking its behavior over time, a basis is provided for identifying the presence of changes in process variability.

Establishing a control chart for ranges R comparable to the \bar{x} -chart requires more specific information about the distribution of the process. In particular, it will be assumed that the individual measurements x are normally distributed. Doing so establishes the relationship between the standard deviation of ranges R and the standard deviation of individual process observations or measurements.

For simplicity, $\pm 3\sigma_R$ limits will be placed about the average range \bar{R} to define the upper and lower control limits for R even though the frequency distribution of ranges is not a symmetric distribution. Obtaining σ_R will be discussed later in this article.

Setting Up \bar{x} and R Control Charts. Once the statistical basis for Shewhart control charts has been established, it remains to define the necessary elements of the charts mathematically and to establish a standard graphical representation. This section deals with the construction of \bar{x} and R control charts. All the necessary equations and general procedures for the calculation and graphical representation of the basic elements of the charts are presented in this section.

The first step in setting up \bar{x} and R control charts is the selection of the samples. It is important that all samples be rational samples. Rational samples are groups of measurements whose variation is attributable only to one constant system of common cause. Sampling from different machines, sampling over extended periods of time, and sampling from product combined from several sources are all nonrational sampling methods and must be avoided. Rational samples will be discussed in more detail later in this article.

As a rule of thumb, 25 to 50 samples should be selected to provide a solid basis for the initiation of the control charts. This will help to ensure more precise estimation of the process mean and standard deviation. The sample/subgroup size should be relatively small (between $n = 3$ and $n = 6$).

With k rational samples of n each, the following steps can be used as a guide when constructing \bar{x} , R control charts with 3σ limits:

- Calculate the sample mean and sample range for each sample using $\bar{x} = \sum x/n$ and $R = x_{\max} - x_{\min}$
- Calculate the grand mean of the n sample means and the average range using $\bar{\bar{x}} = \sum \bar{x}/k$ and $\bar{R} = \sum R/k$
- Calculate the control limits for the R -chart. Although the true distribution of sample ranges is not normal and not symmetric, the symmetric limits are conventionally used for the R -charts. With assumed normal distribution for the individual measurements, the following formulas can be used for the calculation of the control limits: $UCL_R = D_4 \bar{R}$ and $LCL_R = D_3 \bar{R}$
- Calculate the control limits for the \bar{x} -chart. Although the required standard deviation (the standard deviation of the sample mean, \bar{x}) for setting the limits is σ_x , this value is conveniently estimated by $\bar{R}/(d_2 \sqrt{n})$, where d_2 is a function of n . For $3\sigma_{\bar{x}}$ limits, one uses a factor called A_2 , which is equal to $3/(d_2 \sqrt{n})$ and can be found in Table 1. Thus, the control limits are calculated by: $UCL_{\bar{x}} = \bar{\bar{x}} + A_2 \bar{R}$ and $LCL_{\bar{x}} = \bar{\bar{x}} - A_2 \bar{R}$

The appropriate values for d_2 , A_2 , D_3 , and D_4 are obtained from Table 1.

Table 1 Factors for \bar{x} and R control chart limits

Sample size, n	Factors for control limits		Factor for calculating σ_x from range, R d_2

Example 1: Construction of \bar{x} and R Control Charts of an Engine Block Cylinder Bore.

The inside diameter of the cylinder bore in an engine block was measured after a boring operation. Measurements were made to 0.0001 in. Samples of size $n = 5$ were taken to obtain some data to initiate \bar{x} and R control charts for this process. The samples were taken roughly every $\frac{1}{2}$ h. The sample measurements were all taken on the same number cylinder in the

block. The results of the first 20 samples are given in Table 2. The actual measurements are of the form 3.5205 in., 3.5202 in., and so on. Table 2 provides only the last three digits in the measurement.

(a) Sample/subgroup size, $n = 5$.

(b) Although actual cylinder bore data ranged from 3.5187 to 3.5217 in., only the last three digits in the measurement for x , \bar{x} , and R are used.

Determination of Trial Control Limits. Based on these first 20 samples, each sample mean \bar{x} and R was calculated as listed in the last two columns of Table 2. The grand average, $\bar{\bar{x}}$, and average range, \bar{R} , are $\bar{\bar{x}} = 200.62$ and $\bar{R} = 8.5$. For \bar{x} -chart:

$$\begin{aligned} \text{UCL} &= \bar{\bar{x}} + A_2 \bar{R} = 200.62 + (0.58)(8.5) = 205.55 \\ \text{LCL} &= \bar{\bar{x}} - A_2 \bar{R} = 200.62 - (0.58)(8.5) \\ &= 195.69 \end{aligned}$$

For R -chart:

$$\begin{aligned} \text{UCL} &= \bar{R} D_4 = 8.5 (2.11) = 17.935 \\ \text{LCL} &= \bar{R} D_3 = 8.5 (0) = 0.0 \end{aligned}$$

With the above calculations completed, the \bar{x} and R control charts can be constructed. It will be important to start with the R -chart and to get it under statistical control first. This is necessary because the limits of the \bar{x} -chart depend on the magnitude of the common cause variation of the process measured by \bar{R} . If initially some points on the \bar{R} -chart exceed the upper control limit (special causes present), the limits in the \bar{x} -chart will be inflated and will need to be recalculated after such special cause data are removed.

Interpretation of Initial Charts. Figure 15 shows the \bar{x} and R control charts based on the calculations given above. The R -chart is examined first, and it is found that two points exceed the 3σ limit. This indicates that there are special causes (excess process variability) at least at these points. These points--samples 6 and 16--are then examined to identify the reasons for these special causes. The records show that at these points the regular operator was absent and a less-experienced relief operator ran the production for a short time. As a result, samples 6 and 16, taken over the time the relief operator ran the process, exhibited greater variability, perhaps because of inexperience. Because special causes can be identified for samples 6 and 16, these sample values (both \bar{x} and R) are removed and new limits are calculated. The revised centerlines and limits for \bar{x} and R control charts based on the data after samples 6 and 16 have been deleted are shown in Fig. 16.

(b)

Fig. 15 Control charts for inside diameter measurements of engine block cylinder bores in Table 2. (a) \bar{x} -chart.

(b) R -chart. Data are for $k = 20$, $n = 5$.

(a)

(b)

Fig. 16 Revised control charts for Table 2 data with sample 6 and sample 16 data eliminated (both have R values above UCL in Fig. 15) because they are sources of excess process variability. (a) \bar{x} -chart.(b) R -chart. Data now have $k = 18$, $n = 5$.

Interpretation of Revised Charts. Again, the R -chart is examined first. No points are now outside the control limits, and no other unusual patterns of variability appear to be present. The R -chart seems to be in good statistical control. However, examination of the \bar{x} -chart reveals that there are two points above the upper control limit. The investigation of these points reveals the fact that these two samples (1 and 11) occurred at 8:00 a.m. and 1:00 p.m., roughly corresponding to the start-up of the boring machine in the morning and directly after the lunch hour. It was found that the samples were taken from the first few parts made in each case. Once the machine warmed up (approximately 10 min), the problem disappeared. It was decided as a standard policy not to initiate production until 10 min after start-up of the machine.

With this special cause identified and the corresponding values removed, the new limits are calculated. The control charts in Fig. 17 now both show good statistical control. The limits can now be extended, and monitoring of the process can be continued.

(a)

(b)

Fig. 17 Second revision control charts for Table 2 data with two more sample deletions (samples 1 and 11, both of which exceed UCL in Fig. 16) resulting from workpieces produced prior to machine being properly warmed up. (a) \bar{x} -chart. (b) R -chart. Data now have $k = 16$, $n = 5$.

Importance of Using Both \bar{x} and R Control Charts. This example points to the importance of maintaining both \bar{x} and R control charts and the significance of first focusing attention on the R -chart and establishing its stability. Initially, no points fell outside the \bar{x} -chart control limits and one could be led to believe that this indicates that the process mean exhibits good statistical control. However, the fact that the R -chart was initially not in control caused the limits on the \bar{x} -chart to be somewhat wider because of two inordinately large R values. Once these special causes of variability were removed, the limits on the \bar{x} -chart became narrower, and two \bar{x} values now fall outside these new limits. Special causes were present in the \bar{x} data, but initially were not recognizable because of the excess variability as seen in the R -chart.

This example also points strongly to the need to have 25 or more samples before initiating control charts. In this case, once special causes were removed, only 16 subgroups remained to construct the charts. This is simply not enough data.

Importance of Rational Sampling

Perhaps the most crucial issue to the successful use of the Shewhart control chart concept is the definition and collection of the samples or subgroups. This section will discuss the concept of rational sampling, sample size, sampling frequency, and sample collection methods and will review some classic misapplications of rational sampling. Also, a number of practical examples of subgroup definition and selection will be presented to aid the reader in understanding and implementing this central aspect of the control chart concept.

Concept of Rational Sampling. Rational subgroups or samples are collections of individual measurements whose variation is attributable only to one unique constant system of common causes. In the development and continuing use of control charts, subgroups or samples should be chosen in a way that provides the maximum opportunity for the measurements within each subgroup to be alike and the maximum chance for the subgroups to differ from one another if special causes arise between subgroups. Figure 18 illustrates the notion of a rational sample. Within the sample or subgroup, only common cause variation should be present. Special causes/sporadic problems should arise between the selection of one rational sample and another.

Fig. 18 Graphical depiction of a rational subgroup illustrating effect of special causes on mean. (a) Unshifted. (b) Shifted

Sample Size and Sampling Frequency Considerations. The size of the rational sample is governed by the following considerations:

- Subgroups should be subject to common cause variation. The sample size should be small to minimize the chance of mixing data within one sample from a controlled process and one that is out of control. This generally means that consecutive sample selection should be used rather than distributing the sample selection over a period of time. There are, however, certain situations where distributed sampling may be preferred
- Subgroups should ensure the presence of a normal distribution for the sample means. In general, the larger the sample size, the better the \bar{x} distribution is represented by the normal curve. In practice, sample sizes of four or more ensure a good approximation to normality
- Subgroups should ensure good sensitivity to the detection of assignable causes. The larger the sample size, the more likely that a shift of a given magnitude will be detected

When the above factors are taken into consideration, a sample/subgroup size of four to six is likely to emerge. Five is the most commonly used number because of the relative ease of further computation.

Sampling Frequency. The question of how frequently samples should be collected is one that requires careful thought. In many applications of \bar{x} and R control charts, samples are selected too infrequently to be of much use in identifying and solving problems. Some considerations in sample frequency determination are the following:

- If the process under study has not been charted before and appears to exhibit somewhat erratic behavior, samples should be taken quite frequently to increase the opportunity to quickly identify improvement opportunities. As the process exhibits less and less erratic behavior, the sample interval can be

lengthened

- It is important to identify and consider the frequency with which occurrences are taking place in the process. This might include, for example, ambient condition fluctuations, raw material changes, and process adjustments such as tool changes or wheel dressings. If the opportunity for special causes to occur over a 15-min period is good, sampling twice a shift is likely to be of little value
- Although it is dangerous to overemphasize the cost of sampling in the short term, clearly it cannot be neglected

Common Pitfalls in Subgroup Selection. In many situations, it is inviting to combine the output of several parallel and assumed-to-be-identical machines into a single sample to be used in maintaining a single control chart for the process. Two variations of this approach can be particularly troublesome: stratification and mixing.

Stratification of the Sample. Here each machine contributes equally to the composition of the sample. For example, one measurement each from four parallel machines yields a sample/subgroup of $n = 4$, as seen in Fig. 19. In this case, there will be a tremendous opportunity for special causes (true differences among the machine) to occur within subgroups.

Fig. 19 Block diagram depicting a stratified sample selection

When serious problems do arise, for example, for one or more of the machines, they will be very difficult to detect because of the use of stratified samples. This problem can be detected, however, because of the unusual nature of the \bar{x} -chart pattern (recall the previous pattern analysis) and can be rectified provided the concepts of rational sampling are understood.

The R -charts developed from such data will usually show very good control. The corresponding \bar{x} -control chart will show very wide limits relative to the plotted \bar{x} -values, and their control will therefore appear almost too good. The wide limits result from the fact that the variability within subgroups is likely to be subject to more than merely common causes (Fig. 20).

Fig. 20 Typical control charts obtained for a stratified sample selection. (a) \bar{X} -chart. (b) R -chart

Mixing Production From Several Machines. Often it is inviting to combine the output of several parallel machines/lines into a single stream of well-mixed product that is then sampled for the purposes of maintaining control charts. This is illustrated in Fig. 21.

Fig. 21 Block diagram of sampling from a mixture

If every sample has exactly one data point from each machine, the result would be the same as that of stratified sampling. If the sample size is smaller than the number of machines with different means or if most samples do not include data

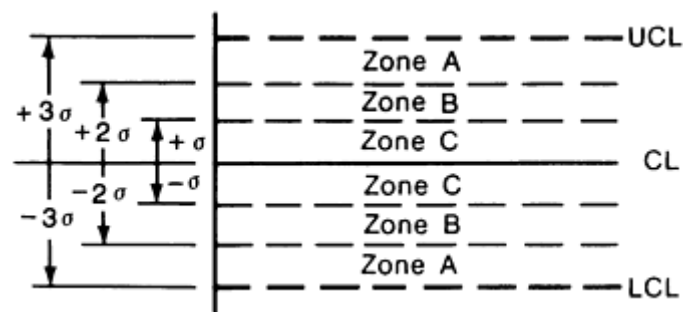

from all machines, the within-sample variability will be too low, and the between-sample differences in the means tend to be large. Thus, the \bar{x} -chart would give an appearance that the \bar{x} values are too far away from the centerline.

Statistical Quality Design and Control

Zone Rules for Control Chart Analysis

Special causes often produce unnatural patterns that are not as clear cut as points beyond the control limits or obvious regular patterns. Therefore, a more rigorous pattern analysis should be conducted. Several useful tests for the presence of unnatural patterns (special causes) can be performed by dividing the distance between the upper and lower control limits into zones defined by σ , 2σ , and 3σ boundaries, as shown in Fig. 22. Such zones are useful because the statistical distribution of \bar{x} follows a very predictable pattern--the normal distribution; therefore, certain proportions of the points are expected to fall within the $\pm\sigma$ boundary, between σ and 2σ , and so on.

The following sections discuss eight tests that can be applied to the interpretation of \bar{x} and R control charts. Not all of these tests follow/use the zones just described, but it is useful to discuss all of these rules/tests together. These tests provide the basis for the statistical signals that indicate that the process has undergone a change in its mean level, variability level, or both. Some of the tests are based specifically on the zones defined in Fig. 22 and apply only to the interpretation of the \bar{x} -chart patterns. Some of the tests apply to both charts. Unless specifically identified to the contrary, the tests/rules apply to the consideration of data to one side of the centerline only.

Fig. 22 Control chart zones to aid chart interpretation

When a sequence of points on the chart violates one of the rules, the last point in the sequence is circled. This signifies that the evidence is now sufficient to suggest that a special cause has occurred. The issue of when that special cause actually occurred is another matter. A logical estimation of the time of occurrence may be the beginning of the sequence in question. This is the interpretation that will be used here. It should be noted that some judgment and latitude should be given. Figure 23 illustrates the following patterns:

- **Test 1 (extreme points):** The existence of a single point beyond zone A signals the presence of an out-of-control condition (Fig. 23a)
- **Test 2 (2 out of 3 points in zone A or beyond):** The existence of 2 out of any 3 successive points in zone A or beyond signals the presence of an out-of-control condition (Fig. 23b)
- **Test 3 (4 out of 5 points in zone B or beyond):** A situation in which there are 4 out of 5 successive points in zone B or beyond signals the presence of an out-of-control condition (Fig. 23c)
- **Test 4 (runs above or below the centerline):** Long runs (7 or more successive points) either strictly above or strictly below the centerline; this rule applies to both the \bar{x} and R control charts (Fig. 23d)
- **Test 5 (trend identification):** When 6 successive points on either the \bar{x} or the R control chart show a continuing increase or decrease, a systematic trend in the process is signaled (Fig. 23e)
- **Test 6 (trend identification):** When 14 successive points oscillate up and down on either the \bar{x} or R control chart, a systematic trend in the process is signaled (Fig. 23f)
- **Test 7 (avoidance of zone C test):** When 8 successive points, occurring on either side of the centerline, avoid zone C, an out-of-control condition is signaled. This could also be the pattern due to mixed sampling (discussed earlier), or it could also be signaling the presence of an over-control situation at the process (Fig. 23g)
- **Test 8 (run in zone C test):** When 15 successive points on the \bar{x} -chart fall in zone C only, to either side of the centerline, an out-of-control condition is signaled; such a condition can arise from stratified

sampling or from a change (decrease) in process variability (Fig. 23h)

The above tests are to be applied jointly in interpreting the charts. Several rules may be simultaneously broken for a given data point, and that point may therefore be circled more than once, as shown in Fig. 24

Fig. 23 Pattern analysis of \bar{X} -charts. Circled points indicate last point in a sequence of points on a chart that violates a specific rule.

Fig. 24 Example of simultaneous application of more than one test for out-of-control conditions. Point A is a violation of tests 3 and 4; point B is a violation of tests 2, 3, and 4; and point C is a violation of tests 1 and 3. See text for discussion.

In Fig. 24, point A is circled twice because it is the end point of a run of 7 successive points above the centerline and the end point of 4 of 5 successive points in zone B or beyond. In the second grouping in Fig. 24, point B is circled three times because it is the end point of:

- A run of 7 successive points below the centerline
- 2 of 3 successive points in zone A or beyond
- 4 of 5 successive points in zone B or beyond

Point C in Fig. 24 is circled twice because it is an extreme point and the end point of a group of five successive points, four of which are in zone B or beyond. Two other points (D, E) in these groupings are circled only once because they violate only one rule.

Statistical Quality Design and Control

Control Charts for Individual Measurements

In certain situations, the notion of taking several measurements to be formed into a rational sample of size greater than one simply does not make sense, because only a single measurement is available or meaningful at each sampling. For example, process characteristics such as oven temperature, suspended air particulates, and machine downtime may vary during a short period at sampling. Even for those processes in which multiple measurements could be taken, they would not provide valid within-sample variation for control chart construction. This is so because the variation among several such measurements would be primarily attributed to variability in the measurement system. In such a case, special control charts can be used. Commonly used control charts for individual measurements include:

- \bar{x} , R_m control charts
- Exponentially weighted moving average (EWMA) charts
- Cumulative sum charts (CuSum charts)

Both the EWMA (Ref 13, 14, 15, 16) and the CuSum (Ref 17, 18, 19, 20, 21) control charts can be used for charting sample means and other statistics in addition to their use for charting individual measurements.

\bar{x} and R_m (Moving-Range) Control Charts. This is perhaps the simplest type of control chart that can be used for the study of individual measurements. The construction of \bar{x} and R_m control charts is similar to that of $\bar{\bar{x}}$ and R control charts except that \bar{x} stands for the value of the individual measurements and R_m for the moving range, which is the range of a group of n consecutive individual measurements artificially combined to form a subgroup of size n (Fig. 25). The moving range is usually comprised of the largest difference in two or three successive individual measurements. The moving ranges are calculated as shown in Fig. 25 for the case of three consecutive measurements used to form the artificial samples of size $n = 3$.

Fig. 25 Examples of three successive measurements used to determine the moving range

Because the moving range, R_m , is calculated primarily for the purpose of estimating common cause variability of the process, the artificial samples that are formed from successive measurements must be of very small size to minimize the chance of mixing data from out-of-control conditions. It is noted that \bar{x} and R_m are not independent of each other and that successive sample R_m values are overlapping.

The following example illustrates the construction of \bar{x} and R_m control charts, assuming that \bar{x} follows at least approximately a normal distribution. Here, R_m is based on two consecutive measurements; that is, the artificial sample size is $n = 2$.

Example 2: \bar{x} and R_m Control Chart Construction for the Batch Processing of White Millbase Component of a Topcoat.

The operators of a paint plant were studying the batch processing of white millbase used in the manufacture of topcoats. The basic process begins by charging a sandgrinder premix tank with resin and pigment. The premix is agitated until a homogeneous slurry is obtained and then pumped through the sandgrinder. The grinder output is sampled to check for fineness and gloss. A batch may require adjustments by adding pigment or resin to achieve acceptable gloss. Through statistical modeling of the results of some ash tests, a quantitative method was developed for determining the amount of pigment or resin to be added when necessary, all based on the weight per unit volume (lb/gal.) of the batch. Therefore, it became important to monitor the weight per unit volume for each batch to achieve millbase uniformity. Table 3 lists weight per unit volume data for 27 consecutive batches.

Table 3 \bar{x} and R_m control chart data for the batch processing of white millbase topcoat component of Example 2

Batch	\bar{x} , lb/gal.	$R_m^{(a)}$
1	14.04	
2	13.94	0.10 (14.04 - 13.94 = 0.10)
3	13.82	0.12 (13.94 - 13.82 = 0.12)
4	14.11	0.29 (14.11 - 13.82 = 0.29)

5	13.86	0.25
6	13.62	0.24
7	13.66	0.04
8	13.85	0.19
9	13.67	0.18
10	13.80	0.13
11	13.84	0.04
12	13.98	0.14
13	13.40	0.58
14	13.60	0.20
15	13.80	0.20
16	13.66	0.14
17	13.93	0.27
18	13.45	0.48
19	13.90	0.45
20	13.83	0.07
21	13.64	0.19
22	13.62	0.02
23	13.97	0.35
24	13.80	0.17
25	13.70	0.10

26	13.71	0.01
27	13.67	0.04
	$\bar{\bar{x}} = 13.77$	$\bar{\bar{R}}_m = 0.19$

(a) Calculated, $n = 2$

In the calculation of averages in Table 3, $\bar{\bar{x}}$ is an average of all 27 individual measurements, while $\bar{\bar{R}}_m$ is an average of 27 - 1 = 26 R_m values because there are only 26 moving ranges for $n = 2$. If the artificial samples were of size $n = 3$, there would be only 27 - 2 = 25 moving averages.

Once the $\bar{\bar{x}}$ and $\bar{\bar{R}}_m$ values are calculated, they are used as centerline values of x and R_m control charts, respectively. The calculation of upper and lower control limits for the R_m control chart is also the same as in $\bar{\bar{x}}$, R control charts, using the artificial sample size n to determine D_3 and D_4 values. However, the upper and lower control limits for the x chart should always be based on a sample size of one, using $\bar{\bar{R}}_m$ the same way as $\bar{\bar{R}}$ in $\bar{\bar{x}}$ control charts. These calculations are shown below for the example data. For the R_m -chart, for $n = 2$, $D_3 = 0$, and $D_4 = 3.27$:

$$\begin{aligned} CL_{R_m} &= \bar{\bar{R}}_m = 4.99/26 = 0.192 \\ UCL_{R_m} &= D_4 \bar{\bar{R}}_m = (3.27)(0.19) = 0.62 \\ LCL_{R_m} &= D_3 \bar{\bar{R}}_m = 0 \end{aligned}$$

For the x -chart, an estimate of the standard deviation of x is equal to $\bar{\bar{R}}_m/d_2$, where $d_2 = 1.128$ from Table 1 using $n = 2$. Thus, $3\sigma = (3/d_2) \bar{\bar{R}}_m = (3/1.128) \bar{\bar{R}}_m = 2.66 \bar{\bar{R}}_m$:

$$\begin{aligned} CL_x &= 13.77 \\ UCL_x &= \bar{\bar{x}} + 2.66 \bar{\bar{R}}_m = 13.77 + (2.66)(0.19) \\ &= 14.28 \\ LCL_x &= \bar{\bar{x}} - 2.66 \bar{\bar{R}}_m = 13.77 - (2.66)(0.19) \\ &= 13.26 \end{aligned}$$

When the individual x values follow a normal distribution, the patterns on the x -chart are analyzed in the same manner as the Shewhart $\bar{\bar{x}}$ -charts. A sample x is circled as a signal of out-of-control values if it falls outside a control limit, if it is the end point of a sequence that violates any of the zone rules, or if it simply indicates a nonrandom sequence. However, tests for unnatural patterns should be used with more caution on an x -chart than on an $\bar{\bar{x}}$ -chart because the individual chart is sensitive to the actual shape of the distribution of the individuals, which may depart considerably from a true normal distribution. Figures 26 and 27 show the x and R_m control charts for the example data.

Fig. 26 R_m control chart obtained for white millbase data in Table 3. Data are for $k = 27$, $n = 2$.

Fig. 27 \bar{x} control chart obtained for white millbase data in Table 3. Data are for $k = 27$, $n = 2$.

Shewhart Control Charts for Attribute Data

Many quality assessment criteria for manufactured goods are not of the variable measurement type. Rather, some quality characteristics are more logically defined in a presence-of or absence-of sense. Such situations might include surface flaws on a sheet metal panel; cracks in drawn wire; color inconsistencies on a painted surface; voids, flash, or spray on an injection-molded part; or wrinkles on a sheet of vinyl.

Such nonconformities or defects are often observed visually or according to some sensory criteria and cause a part to be defined simply as a defective part. In these cases, quality assessment is referred to as being made by attributes.

Many quality characteristics that could be made by measurements (variables) are often not done as such in the interest of economy. A go/no-go gage can be used to determine whether or not a variable characteristic falls within the part specification. Parts that fail such a test are simply labeled defective. Attribute measurements can be used to identify the presence of problems, which can then be attacked by the use of \bar{p} and R control charts. The following definitions are required in working with attribute data:

- *Defect*: A fault that causes an article or an item to fail to meet specification requirements. Each instance of the lack of conformity of an article to specification is a defect or nonconformity
- *Defective*: An item or article with one or more defects is a defective item
- *Number of defects*: In a sample of n items, c is the number of defects in the sample. An item may be subject to many different types of defects, each of which may occur several times
- *Number of defectives*: In a sample of n items, d is the number of defective items in the sample
- *Fractional defective*: The fractional defective, p , of a sample is the ratio of the number of defectives in a sample to the total number of items in the sample. Therefore, $p = d/n$

Operational Definitions

The most difficult aspect of quality characterization by attributes is the precise determination of what constitutes the presence of a particular defect. This is so because many attribute defects are visual in nature and therefore require a certain degree of judgment and because of the failure to discard the product control mentality. For example, a scratch that is barely observable by the naked eye may not be considered a defect, but one that is readily seen is. Furthermore, human variation is generally considerably larger in attribute characterization (for example, three different caliper readings of a workpiece dimension by three inspectors and visual inspection of a part by these same individuals yield anywhere from zero to ten defects). It is therefore important that precise and quantitative operational definitions be laid down for all to observe uniformly when attribute quality characterization is being used. The length or depth of a scratch, the diameter of a surface blemish, or the length of a flow line on a molded part can be specified.

The issue of the product control versus process control way of thinking about defects is a crucial one. From a product control point of view, scratches on an automobile grille should be counted as defects only if they appear on visual surfaces, which would directly influence part function. From a process control point of view, however, scratches on an automobile grille should be counted as defects regardless of where they appear because the mechanism creating these scratches does not differentiate between visual and concealed surfaces. By counting all scratches, the sensitivity of the statistical charting instrument used to identify the presence of defects and to lead to their diagnosis will be considerably increased.

A major problem with the product control way of thinking about part inspection is that when attribute quality characterization is being used not all defects are observed and noted. The first occurrence of a defect that is detected immediately causes the part to be scrapped. Often, such data are recorded in scrap logs, which then present a biased view of what the problem may really be. One inspector may concentrate on scratch defects on a molded part and will therefore tend to see these first. Another may think splay is more critical, so his data tend to reflect this type of defect more frequently. The net result is that often such data may then mislead those who may be using it for process control purposes.

Figure 28 shows an example of the occurrence of multiple defects on a part. It is essential from a process control standpoint to carefully observe and note each occurrence of each type of defect. Figure 29 shows a typical sample result and the careful observation of each occurrence of each type of defect. In Fig. 29, the four basic measures used in attribute quality characterization are defined for the sample in question.

Fig. 28 Typical multiple defects present on an engine valve seat blank to illustrate defect identification in an attribute quality characterization situation

Fig. 29 Analysis of four basic measures of attribute quality characterization used to illustrate the typical defects present in the engine valve seat blank shown in Fig. 28. Out of ten samples tested, four had no defects, three had single defects, and three had multiple defects.

***p*-Chart: A Control Chart for Fraction Defective**

Consider an injection-molding machine producing a molded part at a steady pace. Suppose the measure of quality conformance of interest is the occurrence of flash and splay on the molded part. If a part has so much as one occurrence of either flash or splay, it is considered to be nonconforming, that is, a defective part.

To establish the control chart, rational samples of size $n = 50$ parts are drawn from production periodically (perhaps, each shift), and the sampled parts are inspected and classified as either defective (from either or both possible defects) or nondefective. The number of defectives, d , is recorded for each sample. The process characteristic of interest is the true process fraction defective p . Each sample result is converted to a fraction defective:

$$p = \frac{d}{n} \quad (\text{Eq 1})$$

The data (fraction defective p) are plotted for at least 25 successive samples of size $n = 50$. The individual values for the sample fraction defective, p , vary considerably, and it is difficult to determine from the plot at this point if the variation about the average fraction defective, \bar{p} , is solely due to the forces of common causes or special causes.

Control Limits for the p -Chart. It can be shown that for random sampling, under certain assumptions, the occurrence of the number of defectives, d , in the sample of size n is explained probabilistically by the binominal distribution. Because the sample fraction defective, p , is simply the number of defectives, d , divided by the sample size, n , the occurrence of values for p also follows the binominal distribution. Given k rational samples of size n , the true fraction defective, p' , can be estimated by:

$$\bar{p} = \sum_{i=1}^k p_i / k \quad (\text{Eq 2})$$

or

$$\bar{p} = \sum_{i=1}^k d_i / \sum_{i=1}^k n_i \quad (\text{Eq 3})$$

Equation 3 is more general because it is valid whether or not the sample size is the same for all samples. Equation 2 should be used only if the sample size, n , is the same for all k samples.

Therefore, given \bar{p} , the control limits for the p -chart are then given by:

$$\text{UCL}_p = \bar{p} + 3 \sqrt{\bar{p}(1-\bar{p})/n} \quad (\text{Eq 4a})$$

$$\text{LCP}_p = \bar{p} - 3 \sqrt{\bar{p}(1-\bar{p})/n} \quad (\text{Eq 4b})$$

Thus, only \bar{p} has to be calculated for at least 25 samples of size n to set up a p -chart. The binomial distribution is generally not symmetric in quality control applications and has a lower bound of $p = 0$. Sometimes the calculation for the lower control limit may yield a value of less than 0. In this case, a lower control limit of 0 is used.

Example 3: A p -Chart Applied to Evaluation of a Carburetor Assembly (Ref 22).

This example illustrates the construction of a p -chart. The data in Table 4 are inspection results on a type of carburetor at the end of assembly; all types of defects except leaks were noted, and $n = 100$ for all samples. Samples taken numbered $k = 35$.

Table 4 p -chart data for carburetor assembly of Example 3

Sample, $k^{(a)}$	d	p
1	4	0.04
2	5	0.05

3	1	0.01
4	0	0.00
5	3	0.03
6	2	0.02
7	1	0.01
8	6	0.06
9	0	0.00
10	6	0.06
11	2	0.02
12	0	0.00
13	2	0.02
14	3	0.03
15	4	0.04
16	1	0.01
17	3	0.03
18	2	0.02
19	4	0.04
20	2	0.02
21	1	0.01
22	2	0.02
23	0	0.00

24	2	0.02
25	3	0.03
26	4	0.04
27	1	0.01
28	0	0.00
29	0	0.00
30	0	0.00
31	0	0.00
32	1	0.01
33	2	0.02
34	3	0.03
35	3	0.03

(a) $n = 100$

Using this sample data to establish the p -chart:

$$\bar{p} = \sum_{i=1}^{35} d_i / \sum_{i=1}^{35} n_i = \frac{73}{3500} = 0.02086$$

$$\begin{aligned}\hat{\sigma}_p &= \sqrt{\frac{\bar{p}(1 - \bar{p})}{n}} \\ &= \sqrt{\frac{(0.02086)(1 - 0.02086)}{100}} = 0.01429\end{aligned}$$

$$\begin{aligned}3\hat{\sigma}_p &= 3 \sqrt{\frac{\bar{p}(1 - \bar{p})}{n}} \\ &= 3(0.01429) = 0.04287\end{aligned}$$

Therefore:

$$UCL_p = 0.02086 + 0.04287 = 0.06373$$

$$LCL_p = 0.02086 - 0.04287 = -0.02201$$

That is:

$$LCL_p = 0$$

The plot of the data on the corresponding p -chart is shown in Fig. 30. The process appears to be in statistical control, although eight points lie on the lower control limit. In this case, results of $p = 0$ that fall on the lower control limit should not be interpreted as signaling the presence of a special cause. For a sample size of $n = 100$ and a fraction defective $p' = 0.02$, the binomial distribution gives the probability of $d = 0$ defectives in a sample of 100 to be 0.133. Therefore, a sample with zero defectives would be expected about one out of seven times.

Fig. 30 p control chart obtained for the evaluation of the carburetor assembly data in Table 4. Data are for $k = 35$, $n = 100$.

In summary, the p -chart in this example seems to indicate good statistical control, having no extreme points (outside the control limits), no significant trends or cycles, and no runs of sizable length above or below the centerline. At least over this period of data collection, the process appears to be operating only under a common cause system of variation. However, Fig. 30 shows that the process is consistently operating at a 2% defective rate.

Variable Sample Size Considerations for the p -Chart. It is often the case that the sample size may vary from one time to another as data for the construction of a p -chart are obtained. This may be the case if the data have been collected for other reasons (for example, acceptance sampling) or if a sample constitutes a day's production (essentially

100% inspection) and production rates vary from day to day. Because the limits on a p -chart depend on the sample size n , some adjustments must be made to ensure that the chart is properly interpreted. There are several ways in which the variable sample size problem can be handled. Some of the more common approaches are the following:

- Compute separate limits for each individual subgroup. This approach certainly leads to a correct set of limits for each sample, but requires continual calculation of the control limits and a somewhat messy-looking control chart
- Determine an average sample size, \bar{n} , and a single set of control limits based on \bar{n} . This method may be appropriate if the sample sizes do not vary greatly, perhaps no more than about 20%. However, if the actual n is less than \bar{n} , a point above the control limit based on \bar{n} may not be above its own true upper control limit. Conversely, if the actual n is greater than \bar{n} , a point may not show out of control when in reality it is
- A third procedure for varying sampling size is to express the fraction defective \bar{p} in standard deviation units, that is, plot $(p - \bar{p})/\sigma_p$ on a control chart where the centerline is zero and the control limits are set at ± 3.0 . This stabilizes the plotted value even though n may be varying. Note that $(p - \bar{p})/\sigma_p$ is a familiar form; recall the standard normal (Z) distribution. For this method, the continued calculation of the stabilized variable is somewhat tedious, but the chart has a clean appearance, with constant limits of always ± 3.0 and constant centerline at 0.0

c-Chart: A Control Chart for Number of Defects

The p -chart deals with the notion of a defective part or item where defective means that the part has at least one nonconformity or disqualifying defect. It must be recognized, however, that the incidence of any one of several possible nonconformities would qualify a part for defective status. A part with ten defects, any one of which makes it a defective, is on equal footing with a part with only one defect in terms of being a defective.

Often it is of interest to note every occurrence of every type of defect on a part and to chart the number of defects per sample. A sample may only be one part, particularly if interest is focusing on final inspection of an assembled product, such as an automobile, a lift truck, or perhaps a washing machine. Inspection may focus on one type of defect (such as nonconforming rivets on an aircraft wing) or multiple defects (such as flash, splay, voids, and knit lines on an injection-molded truck grille).

Considering an assembled product such as a lift truck, the opportunity for the occurrence of a defect is quite large, perhaps to be considered infinite. However, the probability occurrence of a defect in any one spot arbitrarily chosen is probably very, very small. In this case, the probability law that governs the incidence of defects is known as the Poisson law or Poisson probability distribution, where c is the number of defects per sample. It is important that the opportunity space for defects to occur be constant from sample to sample. The Poisson distribution defines the probability of observing c defects in a sample where c' is the average rate of occurrence of defects per sample.

Construction of c -Charts From Sample Data. The number of defects, c , arises probabilistically according to the Poisson distribution. One important property of the Poisson distribution is that the mean and variance are the same value. Then given c' , the true average number of defects per sample, the 3σ limits for the c -chart are given by:

$$CL_c = c' \pm 3\sqrt{c'} \quad (\text{Eq 5})$$

Note that the standard deviation of the observed quantity c is the square root of c' . The Poisson distribution is a very simple probability model, being completely described by a single parameter c' .

When c' is unknown, it must be estimated from the data. For a collection of k samples, each with an observed number of defects c , the estimate of c' is:

$$\bar{c} = \sum_{i=1}^k c_i / k \quad (\text{Eq 6})$$

Therefore, trial control limits for the c -chart can be established, with possible truncation of the lower control limit at zero, from:

$$UCL_c = \bar{c} + 3 \sqrt{\bar{c}}$$

$$LCL_c = \bar{c} - 3 \sqrt{\bar{c}}$$

Example 4: c -Chart Construction for Continuous Testing of Plastic-Insulated Wire at a Specified Test Voltage.

Table 5 lists the results of continuous testing of a certain type of plastic-covered wire at a specified test voltage. This test causes breakdowns at weak spots in the insulation, which are cut out before shipment.

Table 5 c -chart data for plastic-insulated wire of Example 4

Sample number, k	Number of breakdowns
1	1
2	1
3	3
4	7
5	8
6	1
7	2
8	6
9	1
10	1
11	10
12	5
13	0
14	19

15	16
16	20
17	1
18	6
19	12
20	4
21	5
22	1
23	8
24	7
25	9
26	2
27	3
28	14
29	6
30	8

The original data consisted of the number of breakdowns in successive lengths of 1000 ft each. There may be 0, 1, 2, 3, . . . , breakdowns per length, depending on the number of weak spots in the insulation. However, so few defects were obtained during a short period of production by using the 1000 ft length as a unit and the expectancy in terms of the number of breakdowns per length was so small that a longer length of 10,000 ft was used for the unit size for the corresponding c -chart. In general, it is desirable to select the sample size for the c -chart application such that on average (\bar{n}) at least one or two defects are occurring per sample.

In most applications, the centerline of the c -chart is based on the estimate of the average number of defects per sample. This estimate can be calculated by:

$$\bar{c} = \frac{\text{Total number of breakdowns}}{\text{Total number of units}} = \frac{187}{30} = 6.23$$

$$\begin{aligned} \text{Control limits: } \bar{c} \pm 3 \sqrt{\bar{c}} &= 6.23 \pm 3 \sqrt{6.23} \\ \text{UCL} &= 13.72 \\ \text{LCL} &= 0 \end{aligned}$$

The resulting c -chart in Fig. 31 shows the presence of special causes of variation.

Fig. 31 c control chart obtained for the evaluation of the plastic-insulated wire data ($k = 30$) in Table 5

u-Chart: A Control Chart for the Number of Defects per Unit

Although in c -chart applications it is common for a sample to consist of only a single unit or item, the sample or subgroup can be comprised of several units. Further, from subgroup to subgroup, the number of units per subgroup may vary, particularly if a subgroup is an amount of production for the shift or day, for example.

In such cases, the opportunity space for the occurrence of defects per subgroup changes from subgroup to subgroup, violating the equal opportunity space assumption on which the standard c -chart is based. Therefore, it is necessary to create some standardized statistic, and such a statistic may be the average number of defects per unit or item where n is the number of items per subgroup. The symbol u is often used to denote average number of defects per unit, that is:

$$u = \frac{c}{n} \quad (\text{Eq 7})$$

where c is the total number of defects per subgroup of n units. For k such subgroups gathered, the centerline on the u -chart is:

$$\bar{u} = \frac{\sum_{i=1}^k c_i}{\sum_{i=1}^k n_i} \quad (\text{Eq 8})$$

$$= \frac{\text{Total defects in } k \text{ subgroups}}{\text{Total number of items in } k \text{ subgroups}}$$

The trial control limits for the u -chart are then given by:

$$CL_u = \bar{u} \pm 3 \sqrt{\bar{u}/n} \quad (\text{Eq 9})$$

Example 5: Use of the u -Chart to Evaluate Leather Handbag Lots.

Table 6 lists inspection results in terms of defects observed in the inspection of 25 consecutive lots of leather handbags. Because the number of handbags in each lot was different, a constant sample size of $n = 10$ was used. All defects were counted even though two or more defects of the same or different type occurred on the same bag. The u -chart data are as follows (Fig. 32):

$$(a) \text{ Centerline } \bar{u} = \frac{382}{250} = 1.53$$

(b) Control Limits for $n = 10$:

$$\bar{u} \pm 3 \sqrt{\bar{u}/n} = 1.53 \pm 3 \sqrt{0.153}$$

$$= 1.53 \pm 1.17$$

$$UCL_u = 2.70$$

$$LCL_u = 0.36$$

Table 6 u -chart data for leather handbag lot production of Example 5

Sample number, $k^{(a)}$	Total number of defects	Defects per unit
1	17	1.7
2	14	1.4
3	6	0.6
4	23	2.3
5	5	0.5
6	7	0.7
7	10	1.0

8	19	1.9
9	29	2.9
10	18	1.8
11	18	1.8
12	5	0.5
13	8	0.8
14	11	1.1
15	18	1.8
16	13	1.3
17	22	2.2
18	6	0.6
19	23	2.3
20	22	2.2
21	9	0.9
22	15	1.5
23	20	2.0
23	20	2.0
25	24	2.4
Total	382	38.2

(a) $n = 10$

Fig. 32 u control chart obtained for the evaluation of leather handbag lot data in Table 6. Data are for $k = 25$, $n = 10$. Datum for sample 9 is an extreme point because it exceeds value of UCL.

Process Capability Assessment

This section presents both traditional and more modern views of process capability and how it is assessed. The presentation stresses the relationship between the control/stability of a process and its capability. The clear distinction between the engineering specification and the statistical control limits in terms of their use and interpretation is emphasized. Using the traditional conformance to the specifications view of process capability, this section illustrates the consequences of a lack of statistical control in terms of the manner and extent to which a process produces parts that meet design intent. This section also presents the loss function approach to the articulation of process capability.

Process Capability Versus Process Control

There are two separate but vitally important issues that must be addressed when considering the statistical representation of process data. These are:

- The ability of the process to produce parts that conform to specifications
- The ability of the process to maintain a state of good statistical control

These two process characteristics are linked in the sense that it will be difficult to assess process capability with respect to conformance to specifications without being reasonably assured of having good statistical control. Although control certainly does not imply conformance, it is a necessary prerequisite to the proper assessment of conformance.

In a statistical sense, conformance to specifications involves the process as a whole; therefore, attention will be focused on the distribution of individual measurements. In dealing with statistical control, summary statistics from each sample, mainly \bar{x} and R , are used; as a result, this involves the distribution of these statistics, not individual measurements.

Because of the above distinction between populations and samples, it is crucial not to compare or confuse part specifications and control limits. In fact, tolerance/specification limits should never be placed on a control chart. This is so because the control chart is based on the variation in the sample means \bar{x} , while it is the individual measurements in the sample that should be compared to specifications. Placing specifications on the control chart may lead to the mistaken impression that good conformance exists when, in fact, it does not. This is illustrated in Example 6.

A process may produce a large number of pieces that do not meet the specified production standards, even though the process itself is in a state of good statistical control (that is, all the points on \bar{x} and R control charts are within the 3σ limits and vary in a random manner). This may be because the process is not centered properly; in other words, the actual mean value of the parts being produced may be significantly different from the specified nominal value of the part. If this is the case, an adjustment of the machine to move the mean closer to the nominal value may solve the problem. Another possible reason for lack of conformance to specifications is that a statistically stable process may be producing parts with an unacceptably high level of common cause variation. In summary, if a process is in statistical control but not capable of meeting the tolerances, the problem may be one of the following:

- The process is off-center from the nominal
- The process variability is too large relative to the tolerances
- The process is off-center and with large variation

Example 6: Statistical Assessment of Process Capability for a Workpiece.

For a certain part, a dimension of interest was specified by the engineering department as 0.140 ± 0.003 in. Many parts were being rejected on 100% inspection using a go/no-go gage because they failed to meet these tolerances.

It was decided to study the capability of the process using \bar{x} and R control charts. These data were taken from the same machine and operator and at the rate of about one sample per hour.

Both the \bar{x} and R control charts seem to indicate good statistical control with no points exceeding the 3σ limits, a reasonably normal distribution of points between the limits, and no discernible trends, cycles, and so on. Therefore, the calculated sample mean $\bar{\bar{x}} = 0.1406$ in. and the sample standard deviation $\sigma_x = 0.0037$ in. are good estimates. The process can then be evaluated with respect to its conformance to specifications.

To obtain a clear picture of the statistical nature of the data, a frequency histogram was plotted that resembled a normal distribution, but the mean appears to be slightly higher than the nominal value of 0.140 set by the engineering department. Figure 33 shows this population distribution curve centered at $\bar{\bar{x}}$ with a spread of $\sigma_x = 0.0037$ in. The specifications are also shown on this plot.

Fig. 33 Normal distribution model for process capability for the data of Example 6. $LSL_x = 0.137$, $USL_x = 0.143$, $\bar{\bar{x}} = 0.1406$, and $\sigma_x = 0.0037$.

The shaded areas in Fig. 33 represent the probability of obtaining a part that does not meet specifications. To compute the probability of a part failing below the lower specification, the standard normal distribution, Z , is calculated, and a normal curve table is used:

$$Z = (x - \bar{\bar{x}}) / \sigma_x$$

where x is the value of either the lower or upper specification, $\bar{\bar{x}}$ is the estimate for the population mean, and σ_x is the estimate of the process standard deviation.

To find the probability of a point below the lower specification limit, $LSL_x = 0.137$, with $\bar{\bar{x}} = 0.1406$, and $\hat{\sigma}_x = 0.0037$:

$$Z = \frac{0.137 - 0.1406}{0.0037} = -0.97$$

Looking this value up in the normal table produces $\text{Prob}(0.137 \text{ or less}) = 0.1660$. This means that there is a 16.6% chance of an individual part falling below the specified tolerance.

To find the probability of an individual part falling above the upper specification limit, $USL_x = 0.143$, $\bar{\bar{x}} = 0.1406$, $\hat{\sigma}_x = 0.0037$, and:

$$Z = \frac{0.143 - 0.1406}{0.0037} = 0.65$$

The probability of a part being above the upper specification limit is equal to 0.2578, based on $Z = 0.65$. The process that does not meet the specifications is therefore $16.6\% + 25.78\% = 42.37\%$.

It might be asked whether centering the process at the nominal value of 0.140 would help. To check, a normal curve is constructed, centered at 0.140. The probability of a point below the lower specification is found by computing Z using the nominal value as the population mean:

$$Z = \frac{0.137 - 0.140}{0.0037} = -0.81$$

Looking up the area for this Z value in the normal curve table produces a value of 0.209, which is the probability of getting a value below the lower specification limit. The probability of getting a value above the upper specification is found by:

$$Z = \frac{0.143 - 0.140}{0.0037} = 0.81$$

which from the normal curve table gives an area = 0.209. The total probability of a part not meeting specification is the sum of these, or $0.209 + 0.209 = 0.41$, or 41%.

Therefore, recentering the process will not be of much help. The process is in control; no special causes of variability were indicated. However, about 42% of the parts were outside the tolerances. Possible remedies include the following:

- Continue to sort by 100% inspection
- Widen the tolerances, for example, 0.140 ± 0.006
- Use a more precise process; reduce process variation
- Use statistical methods to identify variation reduction opportunities for the existing process

Too often, the strategy used (or at least urged) is the second remedy listed above. Clearly, a stronger consideration should be given to the final remedy listed above.

Comparison of Tolerances and Control Limits

It is important to clearly differentiate between specification limits and control limits. The specification limits or tolerances of a part are:

- Characteristic of the part/item in question
- Based on functional considerations
- Related to/compared with an individual part measurement
- Used to establish the conformability of a part

The control limits on a control chart are:

- Characteristic of the process in question
- Based on process variability
- Dependent on sampling parameters, namely, sample size
- Used to identify presence/absence of special cause variation in the process

Control limits and tolerances must never be compared numerically and should not appear together on the same graph. Tolerances are limits on individual measurements and as such can be compared against the process as a whole as represented by many individual measurements collected in the form of a statistical distribution, as was done in Example 6 to assess overall process capability.

Process Capability Indices

It is common to measure process capability in the units of process standard deviations. In particular, it is common to look at the relationship between the process standard deviation and the distance between the upper and lower specification:

$$C_p = \frac{USL_x - LSL_x}{\sigma_x} \quad (\text{Eq 10})$$

The minimum acceptable value for C_p is considered to be 6.

Recently, many companies have begun to use a capability index referred to as C_{pk} . For bilateral specifications, C_{pk} is defined in the following manner. First, the relationship between the process mean \bar{x} and the specification limits in the units of standard deviations is determined:

$$Z_{USL} = \frac{USL - \bar{x}}{\sigma_x} \quad (\text{Eq 11a})$$

$$Z_{LSL} = \frac{LSL - \bar{x}}{\sigma_x} \quad (\text{Eq 11b})$$

Then the minimum of these two values is selected:

$$Z_{\min} = \min[Z_{USL}, -Z_{LSL}] \quad (\text{Eq 12})$$

The C_{pk} index is then defined by dividing this minimum value by 3:

$$C_{pk} = \frac{Z_{\min}}{3} \quad (\text{Eq 13})$$

Commonly, C_{pk} must be ≥ 1.00 .

Statistical Process Control and the Statistical Tolerance Model

The issue of part tolerancing and, in particular, the statistical assignment and assessment of tolerances are excellent examples of the need for design and manufacturing to understand what each other is doing and why. The best intentions of the design process can go unmet if the manufacturing process is not operated in a manner totally consistent with design intent. To more clearly appreciate the marriage of thinking that must exist between the design and manufacturing worlds, some of the basic assumptions of the tolerancing activity and their relationship to the manufacturing process will be examined. The following sections clearly point to the importance of statistical process control relative to the issue of process capability.

The key concepts in statistical tolerancing are:

- The use of a statistical distribution to represent the design characteristic and therefore the process output for the product/part in question relative to the design specifications
- The notion of random assembly, that is, random part selection from these part process distributions when more than one part is being considered in an assembly
- The additive law of variances as a means to determine the relationship between the variability in individual parts and that for the assembly

To assume that the parts can be represented by a statistical distribution of measurements (and for the assumption to hold in reality), the part processes must be in a state of statistical control. The following example illustrates the importance of statistical process control in achieving design intent in a tolerancing problem.

Example 7: Statistical Tolerance Model for Optimum Fit of a Pin Assembly in a Hole Machined in a Plate.

Figure 34 shows two simple parts: a plate with a hole and a pin that will ultimately be assembled to a third part but must pass through the hole in the plate. For the assembly, it is desired for function that the clearance between the plate hole and the pin be at least 0.015 in. but no more than 0.055 in.

Fig. 34 Machined components statistically analyzed in Example 7. (a) Plate with hole. (b) Pin assembly. Dimensions given in inches

To achieve the design requirement stated above, the nominal values and tolerances for the plate hole and pin were statistically derived and are shown in Fig. 34. To arrive at these tolerances, it was assumed that:

- The parts would be manufactured by processes that behave according to the normal distribution
- The process capabilities would be at least 6σ , the processes would be centered at the nominal values given in Fig. 34, and the processes would be maintained in a state of statistical control
- Random assembly would prevail

If these assumptions are met, the processes for the two parts, and therefore the clearance associated with assembled parts, would be as shown in Fig. 35, and the design intent would be met.

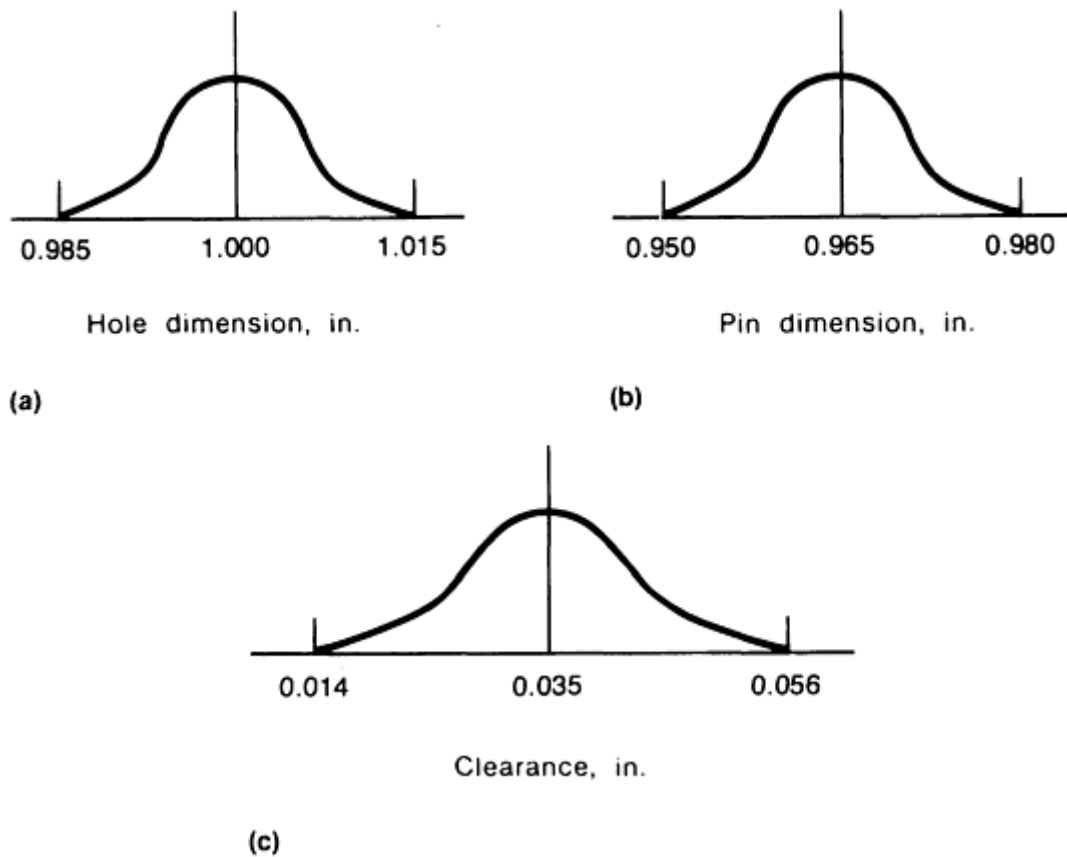

Fig. 35 Statistical basis for satisfying design intent for the hole/pin assembly clearance in Fig. 34. (a) Distribution of hole. (b) Distribution of pin. (c) Distribution of clearance

Suppose that despite the assumptions made and the tolerances derived, the processes manufacturing the pin and plate hole were not maintained in good statistical control. As a result, the parts actually more nearly follow a uniform/rectangular distribution within the specifications, as shown in Fig. 36. Such could have arisen as a result of sorting or rework of a more variable process(es), in which case the results are doubly distressing, that is, poorly fitting assemblies and increased cost to the system.

Fig. 36 Clearance implications of poor process control of plate hole and pin dimensions for components of Fig. 34. (a) Distribution of hole. (b) Distribution of pin. (c) Distribution of clearance

Figure 36 shows the distribution of the clearance if the hole and pin dimensions follow the uniform distribution within the specifications. The additive law of variances has been used to derive the variation in the clearance distributions but assuming the uniform distribution for the individual part processes. Some assemblies may not go together at all, some will fit quite tightly and may later bind if foreign matter gets into the gap, and others will fit together with a much larger clearance than desired.

The problem here is not a design problem. The plate hole and pin tolerances have been derived using sound statistical methods. However, if the processes are not in good statistical control and therefore not capable of meeting the assumptions made during design, poor-quality assemblies will follow. It should be noted that the altogether too common process appearance of a uniform distribution of measurements within the specifications can arise in several different ways:

- From processes that have good potential with regard to variation, but are not kept in good statistical control
- From unstable and/or large variation processes that require sorting/rework to meet the specifications
- From processes that are intentionally allowed to vary over the full range of the specifications to take advantage locally of wide specifications relative to the process variation

In all of the three cases mentioned above, additional costs will be incurred and product quality will be eroded. Clearly, statistical process control is crucial to the tolerancing issue in engineering design. Taguchi's loss function model, which is an essential element in tolerance design, assumes similarly that quality characteristics can be represented by a statistical distribution of measurements. Again, for this assumption to be met at the process and therefore in the ultimate product in the field, the manufacturing processes must be maintained in a state of statistical control.

Design of Experiments: Factorial Designs

The process of product design and its associated manufacturing processes and tolerance designs often involve many experiments to better understand the various cause-effect relationships for quality performance of the product and for ease in process control. The sections that follow will present some of the basic concepts and methods for the planning, design, and analysis of experiments.

The purpose of most experimental work is to discover the direction(s) of change that may lead to improvements in both the quality and the productiveness of a product or process. Such endeavors can be referred to as process improvement because product improvement can only be meaningfully measured through its use and that is of course a process. Historically, design of experiments methods have tended to focus more attention on process improvement as contrasted with product design. In this regard, the different view that might be taken toward design of experiments in product design versus processing is probably overstated. In this section, the role of design of experiments in product design is emphasized, as is its use in the simultaneous engineering of products and processes.

In investigating the variation in performance of a given product or process, attention focuses on the identification of those factors that, when allowed to vary, cause performance to vary in some way. Some such factors are qualitative in nature (categorical variables), while others are quantitative (possessing an inherent continuity of change). The situations examined below may consider both qualitative and quantitative variables simultaneously. In fact, an important advantage of the two-level factorial designs that will be discussed is their ability to consider both types of variables within the same test plan.

Mathematical Model

A fundamental problem of design of experiments is that of selecting the appropriate arrangement of test points within the space defined by the design/control and noise variables. Although many different considerations must come into play in selecting a test plan, none can be more fundamental than the notion of the mathematical model. Whether or not explicitly recognized as such, most experimental studies are aimed either directly or indirectly at discovering the relationship between some performance response and a set of candidate variables influencing that response. In general, this relationship can be written as:

$$Y = f(X_1, X_2, \dots, X_k) + e \quad (\text{Eq 14})$$

where Y is the response of interest, f is some unknown functional relationship, X_1, \dots, X_k are the independent variables, and e is a random error. The functional form f can be thought of as a transfer function. In Taguchi's framework, the variables X_1, X_2, \dots, X_k are generally partitioned into signal, control, and noise variables.

Sometimes enough is known about the phenomenon under study to use theoretical considerations to identify the form of f . For example, a chemical reaction can be described by a differential equation, which when solved produces a theoretical relationship between the dependent and independent variables. More often than not, however, the knowledge is more sparse, and empirical models must be relied upon that act as mathematical french curves describing relationships through the data; for example:

$$Y = b_0 + b_1X_1 + b_2X_2 + e \quad (\text{Eq 15a})$$

$$Y = b_0 + b_1X_1 + b_{11}X_1^2 + e \quad (\text{Eq 15b})$$

Model Building. In most studies, the experimenter begins with a tentative hypothesis concerning the plausible model forms that are to be initially entertained. He must then select an experimental design having the ability to produce data that will:

- Be capable of fitting proposed model(s)
- Be capable of placing the model in jeopardy in the sense that inadequacies in the model can be detected through analysis

The second consideration above is of particular importance to ensure that through a series of iterations the most appropriate model can be determined, while others may be proved less plausible through the data.

If, for example, a curvilinear relationship between temperature and reaction time in a chemical process is suspected, an experiment that studies the process at only two temperatures will be inadequate to reveal this possibility. An experiment with three levels of temperature would, however, allow this possibility to be considered. Figure 37 illustrates several scenarios that emphasize the importance of the relationship between the math model and the associated design of experiment. In Fig. 37, the following points should be noted:

- The relationship is actually curvilinear, but such will never be detected by the data
- A poor model (straight line) has been hypothesized, but model checking can reveal this and help propose a better model
- If the relationship is known to be a straight line, many levels of temperature in the experiment are unnecessary
- If it is known *a priori* that the relationship is a straight line, the best test plan would be to study only two relatively extreme levels of temperature and to use additional tests for replication to observe the amount of experimental error

Fig. 37 Comparison of typical time-temperature relationships for true relationship (a) compared to experimental and fitted models (a through d. See text for more details.)

Sequential and Iterative Experimentation. There is always the temptation to carefully design one large experiment that will consider all aspects of the problem at hand. Such a step is dangerous for the following reasons:

- If erroneous decisions and hypotheses about the state of affairs are made, considerable time and experimental resources may be wasted, and the end product may provide little useful information or direction in terms of what to do next
- If knowledge of the underlying situation is limited *a priori*, many factors may be suspected as being important, requiring a very large experiment in terms of number of tests. Ultimately, only a small subset of variables will be found to be of major significance
- In the early stages of experimentation, knowledge of the specific ranges of variables that ought to be studied is not always available. Furthermore, the metrics to be employed to define the variables, responses, or even what responses to observe may not always be clear in the early stages of experimental work
- One large experiment will necessarily cause the testing period to be protracted in time, making it more

difficult to control the forces of nuisance variation

For these reasons, it is much more desirable to conduct an experimental program through a series of smaller, often interconnected experiments. This provides the opportunity to modify hypotheses about the state of affairs concerning the situation at hand, to discard variables that are shown to be unimportant, to change the region of study of some or all of the variables, and/or to define and include other measures of process performance. Experimental designs that can be combined sequentially are very useful in this regard. This is often referred to as the sequential assembly of experimental designs.

Revelation of Variable Effects. Often, the variables of importance are not clearly known *a priori*. It is desirable to be able to study several variables together but to independently observe the effect of a change in each one of the variables. Furthermore, it may be deemed important to know if such a variable effect varies with the conditions of the process, that is, when other variables take on varying levels. An arrangement of the tests is called a design, which provides for the opportunity to learn much about the relationships between the variables and the response. In particular:

- The effect of changing any of the variables alone can be observed
- The possibility that the effects measured above can vary as conditions of other variables vary can be observed, that is, the existence of variable interactions

System Noise/Variation

The experimental study of any phenomenon is made difficult by the presence of noise or experimental error. Many factors, not directly under study, are varying over the course of the experiment. These are often referred to as the forces of common cause system variation. Such variation may cloud or mask the effect of change of the factors under study in an experiment. The forces of noise or variation can be better understood or mitigated by several approaches, some of which are strictly experimental design issues.

Statistical Control/Stability Analysis. If the phenomenon under study is already a viable and ongoing process, the pursuit of improvement opportunities through experimentation can be considerably enhanced by employing the techniques of statistical process control. In this way, spurious or sporadic sources of variation can be identified and, through remedial action, removed. Achievement of a stable process will greatly contribute to the ability to more readily observe the effects of purposeful process change. Thus, continued study will further enhance the ability to observe the persistence of changes that might be introduced. Once a process is stabilized, continued attack on the common cause system will lead to a progressively quieter process, further heightening the ability to observe the forces of purposeful process change through experimentation.

Experimental Design Strategies. In many situations, the notion of a stable, ongoing process has little meaning. In the early stages of product or process design or prototype or pilot-plant testing, a stable, consistent process is not present. It is perhaps for this reason (among others) that the body of knowledge known as experimental design was cultivated. Under such situations, the following factors are significant:

- Attempt to identify major sources of variation and take action to ensure that their presence is blocked out from the comparisons made within an experiment. The technique of blocking is useful for this purpose
- Counteract the forces of unknown systematic variation over the period of the experiment by randomization of the tests so that such variation is uniformly and randomly distributed across the trials conducted
- Include replication in the experimental test plan. Multiple tests at the same conditions will provide comparisons that directly measure the amount of variation/experimental error
- Include confirmatory testing as part of the experimental strategy. It will be important that additional trials are run under specific conditions determined from the analysis to verify the improvement opportunities revealed from the experiment

The parameter design method is specifically directed at mitigating the forces of noise variation as it may be transmitted through the product/process design to the output performance.

Nature of Variable Interactions

For many products and/or processes, the effects that the important design/control factors have on the system performance responses of interest do not act independently of each other. That is, the effect a certain factor has on the response may be different for different levels of a second factor. When this occurs, the two factors are said to interact or to have an interdependency relationship; that is, a two-factor interaction effect is present. Figure 38 summarizes the nature of the two-factor interaction effect. Figure 38(a) shows that the effect of pressure on time (the slope of the line) is the same regardless of the level of temperature. Therefore, no interaction is present. However, in Fig. 38(b), the effect of pressure on time is clearly seen to vary with temperature. Therefore, a two-factor interaction is present.

Fig. 38 Graphical depiction of the absence (a) and presence (b) of a two-factor interaction effect

Simple Yet Powerful Experimental Design. Many of the problems created by *ad hoc* testing methods and/or methods such as the one-variable-at-a-time approach can be overcome by using an experimental design structure referred to as the two-level factorial design. For such test plans, each factor/variable is studied over only two levels or settings, and all possible combinations are examined. Therefore, the total number of unique tests required for such a test plan is 2^k , where k is the number of variables; for example, for two variables, $2^2 = 4$ test conditions define the test matrix.

Figure 39 shows a graphical representation of the two-level factorial design when two and three variables are under study. The geometric representation is useful from the standpoints of interpreting the variable effects and communicating the purpose and results of the test plan to others. The corners of the square and the cube represent geometrically the conditions of each unique combination of the variable settings.

Fig. 39 Two-level factorial design for two (four tests required) (a) and three (eight tests required) (b) variables

Tables 7(a) and 7(b) provide for a more algebraic way to represent the test conditions for a two-level factorial design. The two levels for each factor are often simply referred to as the high and low levels and are represented in coded form as + or +1 and - or -1. This facilitates the determination of the variable effects, given the data. Each row in Tables 7(a) and 7(b) represents the recipe for a particular test. For example, in the 2^3 factorial in Table 7(b), test 3 is run with variable 1(X_1) at its low level, variable 2(X_2) at its high level, and variable 3(X_3) at its low level.

Statistical Quality Design and Control

Richard E. DeVor, University of Illinois, Urbana-Champaign; Tsong-how Chang, University of Wisconsin, Milwaukee

Experimental Study Using a 2³ Factorial Design

Example 8: Use of 2³ Factorial Design to Determine Need for Preheating or Postheating of Welded High-Carbon Steel Rail Bars (Ref 23).

High-carbon steel, because of its high strength and low cost, has been extensively used for railway track. The Rail Steel Bar Association sponsored a research project at the Welding Research Laboratory of the University of Wisconsin around 1960 to study whether or not preheating and postheating were necessary for the high-carbon steel to have good-quality welds. After a preliminary investigation by manual arc-welding tests, it appeared that there were three variables affecting the ultimate tensile stress of a weld. Based on the needs of the study and the available funds, it was suggested to run 16 tests that were defined according to a 2³ factorial design. The three selected variables and their high and low levels are shown below:

Variable	Low level	High level
Ambient temperature (<i>T</i>), °F	0	70
Wind velocity (<i>V</i>), mph	0	20
Bar size (<i>B</i>), $\frac{1}{8}$ in.	4	11

First, the variables are coded such that the high level will be denoted by +1 and the low level by -1. By so doing, regardless of the physical conditions represented by the two levels, the basic design of any two-level factorial design becomes a simple arrangement of plus or minus ones. Writing down three columns of the plus and minus ones next to one another produces the desired 2³ factorial design, which consists of the 8 distinct sets of coded test conditions, as indicated

in Table 8. The 8 sets of coded test conditions are given by the 8 rows corresponding to test numbers 1 to 8. These constitute the recipes for running the tests. For example, the actual welding conditions for test number 1 (which is denoted by -1, -1, -1) were a temperature of 0 °F, a wind velocity of 0 mph, and a bar size of $\frac{1}{2}$ in.

Table 8 Coded test conditions based on actual test conditions for the steel rail bars of Example 8

Test number	Actual test conditions			Coded test conditions		
	Temperature, °F	Wind velocity, mph	Bar size, $\frac{1}{8}$ in.	X_1	X_2	X_3
1	0	0	4	-1	-1	-1
2	70	0	4	+1	-1	-1
3	0	20	4	-1	+1	-1
4	70	20	4	+1	+1	-1
5	0	0	11	-1	-1	+1
6	70	0	11	+1	-1	+1
7	0	20	11	-1	+1	+1

Geometric Representation of 2^3 Factorial Design. If the three variables are considered to be three mutually perpendicular coordinate axes X_1 , X_2 , and X_3 , the 2^3 factorial design can be represented geometrically as a cube, as shown in Fig. 40. The circled numbers at the 8 corner points of the cube represent the corresponding test numbers in standard order. The 8 actual test conditions are given in brackets. This geometric configuration will be useful later when the average and interaction effects of the variables are calculated and when the average/main effect and two- and three-factor interaction effects are interpreted.

Fig. 40 Geometric representation of the 2^3 factorial design

Test Conduct: Random Order and Replication. In performing experiments, randomization of the test order should be exercised wherever possible. This is important because the standard order discussed previously is a very systematic ordering of the tests in terms of the patterns of the levels of the variables from test to test. In this example, there are 8 test conditions, each of which was replicated once for a total of 16 tests. The main purpose of conducting replicated tests is to provide an estimate of the experimental error of the test method. The observed responses of these welding experiments were the ultimate tensile stresses of the welds. Because of replication, 2 responses (y_{ai} , y_{bi}) were observed at each of the 8 distinct sets of test conditions. Therefore, there were a total of 16 responses (Table 9).

Table 9 Results of the 16 welding experiments for the steel rail bars of Example 8

Because of replication, two responses (y_{ai} , y_{bi}) were observed for each of the eight distinct sets of test conditions.

i	X_1	X_2	X_3	Replicate 1 Order of		Replicate 2 Order of		Average, \bar{y}
				y_{ai}	y_{bi}	y_{bi}	y_{ai}	
1	-1	-1	-1	6	84.0	3	91.0	87.5

2	+1	-1	-1	8	90.6	7	84.0	87.3
3	-1	+1	-1	1	69.6	5	86.0	77.8
4	+1	+1	-1	2	76.0	4	98.0	87.0
5	-1	-1	+1	5	77.7	8	80.5	79.1
6	+1	-1	+1	3	99.7	1	95.5	97.6
7	-1	+1	+1	4	82.7	2	74.5	78.6
8	+1	+1	+1	7	93.7	6	81.7	87.7

The tests were performed in a random fashion, as indicated by the test order. The average of the 2 responses observed at each set of test conditions (that is, $y_{ai} + y_{bi}/2$, denoted by \bar{y}_i) was determined, and the 8 average responses (\bar{y}_i , where $i = 1, 2, \dots, 8$) are given in the far right-hand column of Table 9. These average responses will be used to calculate the average main and average interaction effects for the variables under study.

Calculation of Variable Effects on Weld Strength. Given the results in Table 9, it is possible to evaluate the individual and joint influences of ambient temperature, wind velocity, and bar size on the ultimate tensile stress of the weld. To help determine what these variable effects are, what they mean, and how they can be calculated, the geometrical representation of the experimental design is used. The cube shown in Fig. 41 depicts the 2^3 design geometrically. The average response (ultimate tensile strength) for each test is given at the corners of the cube.

Fig. 41 Geometric representation of the effect on ultimate tensile stress, given at the corners of the cube, of changes in ambient temperature when wind velocity and bar size are held constant

Calculation of Average Main Effects. As Fig. 41 shows, there are four comparisons of test results or contrasts that indicate how ultimate tensile stress changes when ambient temperature changes, with wind velocity and bar size being held constant. The effect of ambient temperature alone can be determined by looking across the cube from left to right. The differences in the results within each of the 4 pairs of tests reflect the effect of ambient temperature alone on ultimate tensile stress. The differences in units of ksi are:

- Test No. 1 and 2: $\bar{y}_2 - \bar{y}_1 = 87.3 - 87.5 = -0.2$
- Test No. 3 and 4: $\bar{y}_4 - \bar{y}_3 = 87.0 - 77.8 = 9.2$
- Test No. 5 and 6: $\bar{y}_6 - \bar{y}_5 = 97.6 - 79.1 = 18.5$
- Test No. 7 and 8: $\bar{y}_8 - \bar{y}_7 = 87.7 - 78.6 = 9.1$

The average effect of ambient temperature, designated by E_1 , is defined as the average of the above four differences. Note that this average effect is also commonly referred to as a main effect. That is:

$$E_1 = \frac{1}{4}[(\bar{y}_2 - \bar{y}_1) + (\bar{y}_4 - \bar{y}_3) + (\bar{y}_6 - \bar{y}_5) + (\bar{y}_8 - \bar{y}_7)]$$

$$E_1 = \frac{1}{4}[(-0.2) + (9.2) + (18.5) + (9.1)]$$

$$E_1 = 9.15 \text{ ksi}$$

Geometrically, the average (main) effect of ambient temperature, E_1 , is the difference between the average test result on plane II (high level of ambient temperature) and the average test result on plane I (low level of ambient temperature), as shown in Fig. 41.

The average effect of ambient temperature indicated that, on the average, over the ranges of the variables studied in this investigation, the effect of changing the ambient temperature from its low level to its high level is to increase the ultimate tensile stress by 9.150 ksi. However, the individual differences (0.2, 9.2, 18.5, and 9.1 ksi) are actually quite erratic. The average effect, therefore, must be interpreted with considerable caution because this effect is not particularly consistent over the four unique combinations of wind velocity and bar size.

Again, referring to Fig. 41, the following pairs of tests can be compared or contrasted to determine the effect of wind velocity. The average effect of wind velocity, E_2 can be obtained by taking the average of the four individual differences, which are in units of ksi:

- Test No. 1 and 3: $\bar{y}_3 - \bar{y}_1 = 77.8 - 87.5 = -9.7$
- Test No. 2 and 4: $\bar{y}_4 - \bar{y}_2 = 87.3 - 87.0 = -0.3$
- Test No. 5 and 7: $\bar{y}_7 - \bar{y}_5 = 78.6 - 79.1 = -0.5$
- Test No. 6 and 8: $\bar{y}_8 - \bar{y}_6 = 87.7 - 97.6 = -9.9$

The value E_2 for tests 1 to 8 is calculated as follows:

$$E_2 = \frac{1}{4}[(\bar{y}_3 - \bar{y}_1) + (\bar{y}_4 - \bar{y}_2) + (\bar{y}_7 - \bar{y}_5) + (\bar{y}_8 - \bar{y}_6)]$$

$$E_2 = \frac{1}{4}[(-9.7) + (-0.3) + (-0.5) + (-9.9)]$$

$$= -5.1 \text{ ksi}$$

Similarly, the average effect of bar size, E_3 , is 0.85 ksi.

Interpretation of Average/Main Effects. The average or main effect of a variable has been defined as the amount of change observed in the response, on the average, when only that variable changes from its low to high value or level. It is an average effect because within the experimental design there are generally several comparisons or contrasts that can

be made that measure how much the response changes when only a certain variable changes. The sign and the magnitude of an average/main effect have the following meaning:

- The sign indicates the direction of the effect
- The magnitude indicates the strength of the effect

If the numbers comprising this average are quite similar in magnitude (and of course, sign), the effect of that particular variable would appear to be independent of the particular level(s) of other variable(s). However, if the numbers comprising this average are quite different in magnitude (or even sign), the effect of that particular variable depends on the level(s) that the other variable(s) assumes. In this case, the average/main effect does not hold much significance, and the response of interest must be examined when two or more variables change simultaneously.

Meaning of Variable Interactions. In calculating the average/main effect of ambient temperature, the amount (and even direction) of change in weld strength with change in temperature seemed to depend quite heavily on the particular levels of wind velocity and bar size:

Wind velocity, mph	Bar size, in.	Effect of temperature on weld strength, ksi
0	$\frac{4}{8}$	-0.2
20	$\frac{4}{8}$	+9.2
0	$\frac{11}{8}$	+18.5
20	$\frac{11}{8}$	+9.1

What is the particular nature of the dependency of the effect of temperature on wind velocity and bar size? The degree of dependency of the temperature effect on the particular levels of wind velocity and bar size can be appreciated via the following graphical summaries. Referring to the geometrical representation of the 2^3 factorial in Fig. 41, the interaction between temperature and wind velocity can be examined by compressing the cube in the bar size direction as shown in Fig. 42(a). Compressing the cube means that the response values for a given temperature and wind velocity combination--for example, (-), (-)--are averaged across the high and low levels of bar size. The result is that the cube (Fig. 42a) becomes a square (Fig. 42b). Similarly, the other two interactions are found to be:

$$\begin{aligned}
 E_{13} &= [(92.65 - 78.85) - (87.15 - 82.65)]/2 \\
 &= 4.65 \text{ ksi} \\
 E_{23} &= [(83.15 - 82.40) - (88.35 - 87.40)]/2 \\
 &= -0.10 \text{ ksi}
 \end{aligned}$$

Fig. 42 Two-factor interaction between temperature and wind velocity obtained by compressing three-dimensional cube (a) in the bar size direction to obtain two-dimensional square plane (b)

A Simplified Method for Main and Interaction Effects. Although the geometrical representation of the experimental design has been quite useful, a simpler and more general method will be needed for calculation of the variable main and interaction effects. A simplified calculation procedure, which is easily extended for analyzing two-level factorial designs in any number of variables, is described below.

The mathematical model form associated with a 2^2 factorial is:

$$Y = b_0 + b_1X_1 + b_2X_2 + b_{12}X_1X_2 + e$$

where the coefficients b_1 and b_2 correspond to the average/main effects of variables 1 and 2, respectively, and the coefficient b_{12} corresponds to the interaction effect between variables 1 and 2.

Referring to the design matrix for Example 8 (Table 9), estimates of the interaction effects E_{12} , E_{13} , E_{23} , and E_{123} can be obtained by forming the cross-product columns X_1X_2 , X_1X_3 , X_2X_3 , and $X_1X_2X_3$, as indicated in Table 10. This complete seven-column matrix will be referred to as the calculation matrix. The cross-product columns of \pm signs are simply the inner-products of the individual columns, for example, $X_1X_2 = (X_1)(X_2)$.

Table 10 Calculation matrix for the data obtained for the steel rail bars of Example 8

Test	Main effects			Interactions				\bar{y}
	X_1	X_2	X_3	X_1X_2	X_1X_3	X_2X_3	$X_1X_2X_3$	
1	-1	-1	-1	+1	+1	+1	-1	87.5
2	+1	-1	-1	-1	-1	+1	+1	87.3
3	-1	+1	-1	-1	+1	-1	+1	77.8
4	+1	+1	-1	+1	-1	-1	-1	87.0
5	-1	-1	+1	+1	-1	-1	+1	79.1
6	+1	-1	+1	-1	+1	-1	-1	97.6
7	-1	+1	+1	-1	-1	+1	-1	78.6

To calculate any one of the average effects or interactions, merely multiply, element by element, the appropriate column by the column of average responses, sum algebraically, and divide the sum by 4 (that is, $2^3/2$; in general, for a 2^k factorial design, the sum should be divided by $2^{k/2}$). For example, to calculate the average effect of ambient temperature, E_1 , it is necessary to proceed as indicated in Table 11. The sum is 36.6×10^3 psi or 36.6 ksi, which, when divided by 4, yields 9.150 ksi for the average effect of temperature, the same answer obtained previously.

Table 11 2^k factorial design calculation of the average effect of ambient temperature on steel rail bar ultimate tensile strength in Example 8

X_1	\bar{y}_i			$X_1\bar{y}_i$		$X_1\bar{y}_i$
-1	87.5		(-1)	(87.5)		-87.5
+1	87.3		(+1)	(87.3)		+87.3
-1	77.8		(-1)	(77.8)		-77.8
+1	87.0	=	(+1)	(87.0)	=	+87.0

-1	79.1		(-1)	(79.1)		-79.1
+1	97.6		(+1)	(97.6)		+97.6
-1	78.6		(-1)	(78.6)		-78.6
+1	87.7		(+1)	(87.7)		+87.7
				Sum	=	+36.6

The two-variable and three-variable interactions can be calculated by the same method (Table 12). For example, to calculate the interaction between ambient temperature and wind velocity, E_{12} , multiply the column X_1X_2 by the column of \bar{y}_i , sum algebraically, and then divide the sum by $2^3/2 = 4$. Dividing the sum by 4 yields the answer obtained previously (namely, 0) for this two-variable interaction.

Table 12 2^k factorial design calculation of interaction between ambient temperature and wind velocity on steel rail bar ultimate tensile strength in Example 8

X_1X_2	\bar{y}_i		X_1X_2	\bar{y}_i		$X_1X_2\bar{y}_i$
+1	87.5		(+1)	(87.5)		+87.5
-1	87.3		(-1)	(87.3)		-87.3
-1	77.8		(-1)	(77.8)		-77.8
+1	87.0	=	(+1)	(87.0)	=	+87.0
+1	79.1		(+1)	(79.1)		+79.1
-1	97.6		(-1)	(97.6)		-97.6
-1	78.6		(-1)	(78.6)		-78.6
+1	87.7		(+1)	(87.7)		+87.7
				Sum	=	0.0

Judging the Importance of Average Effects. To judge the relative importance of a variable effect based on the calculated average effects and interactions, it is necessary to make use of the test replications to estimate the error expected in an effect estimate. In particular, it is necessary to:

- Estimate the experimental error via the variance of an individual observation

- Estimate the error/variance associated with an average effect and/or interaction effect, either of which is simply a linear combination (sum) of several individual observations
- Construct the statistical distribution of effect estimates and examine the range of estimates that could arise

Figure 43 shows a graphical depiction of what could arise from the above-mentioned test replications. In case 1 (Fig. 43a), the effect estimates could easily arise from a distribution with a mean of zero. In case 2 (Fig. 43b), the implication is that they could not. The above procedures come under the heading of what is commonly referred to as a statistical test of significance. The two most common approaches in this regard are the hypothesis-testing method and the confidence interval method. Additional information is available in Ref 8 and 24.

Fig. 43 Judging the relative importance of a variable effect. (a) Effect not important. (b) Effect important. Open circles represent effect estimates based on multiple experiment results.

Confidence Interval Method. Each of the 8 tests in Example 8 was replicated once (Table 9), so that there were actually 16 individual observations on the ultimate tensile stress. The error or variance of each of these 16 observations will now be estimated. The amount of error in an observation is assumed to be about the same for all observations; that is, the true variance is the same for all 16 observations, and the observations are independent.

For test 1, the two observations are 84.0 ksi and 91.0 ksi. A sample variance for this test condition, designated as s_1^2 , can be calculated in the usual way:

$$s_1^2 = \frac{(y_{a1} - \bar{y}_1)^2 + (y_{b1} - \bar{y}_1)^2}{2 - 1} = 24.50$$

In this example, 8 different and completely independent sample variances ($s_1^2, s_2^2, \dots, s_8^2$) are calculated, 1 for each unique test condition. The 8 sample variances are calculated to be:

$s_1^2 = 24.50$
$s_2^2 = 21.78$
$s_3^2 = 134.48$

$s_4^2 = 242.00$
$s_5^2 = 3.92$
$s_6^2 = 8.82$
$s_7^2 = 33.62$
$s_8^2 = 72.00$

Because there is assumed to be a common variance for all 16 observations, an estimate for the variance is the pooled sample variance s_P^2 , of the 8 estimated variances $s_1^2, s_2^2, \dots, s_8^2$. In this case:

$$s_P^2 = \frac{[(y_{a1} - \bar{y}_1)^2 + (y_{b1} - \bar{y}_1)^2] + \dots + [(y_{a8} - \bar{y}_8)^2 + (y_{b8} - \bar{y}_8)^2]}{(2 - 1) + \dots + (2 - 1)} \quad (\text{Eq 16})$$

$$s_P^2 = \frac{24.50 + 21.78 + \dots + 72.00}{8} = 67.64$$

In general, an effect is determined from:

$$E = \frac{2}{N}[y_1 + y_2 + \dots + y_N] \quad (\text{Eq 17})$$

where N is the total number of unique test/trial results.

In this general case, the variance of an effect is given by:

$$\sigma_{\text{effect}}^2 = \frac{4\sigma_x^2}{N} \quad (\text{Eq 18})$$

An estimate of the variance of an effect (s_{effect}^2) is obtained by substituting the pooled sample variance, s_P^2 , for σ_x^2 .

A confidence interval for a certain parameter can be calculated on the basis of the sample statistic. Here the statistics of interest are the average effects, E_1, E_2, E_3 , and the interactions, E_{12}, E_{13}, E_{23} , and E_{123} . Because the sample variances of the average effects and interactions are all estimated by $s_P^2/4$, the result, for $100(1 - \alpha)\%$ confidence intervals using the Student's t-statistic, is:

$$E \pm t_{(v, 1 - \alpha/2)} \sqrt{\frac{s_P^2}{4}} \quad (\text{Eq 19})$$

where $\nu = 8$ is the degree of freedom and $\alpha = 0.05$ is the level of significance. Therefore, the 95% confidence intervals for each of the sample average effects are therefore:

$$E \pm 2.306 \sqrt{\frac{67.64}{4}} = E \pm 9.48$$

Table 13 gives the seven statistics (E_1 , E_2 , E_3 , E_{12} , E_{13} , E_{23} , and E_{123}) together with their corresponding 95% confidence intervals. From Table 13, it would appear that none of the estimated effects is important/significant.

Table 13 Calculation of 95% confidence levels for average effect and interaction statistics of steel rail bars of Example 8

Average effects	95% confidence interval, psi
Ambient temperature (E_1)	9150 ± 9480
Wind velocity (E_2)	-5100 ± 9480
Bar size (E_3)	850 ± 9480
Ambient temperature × wind velocity (E_{12})	0 ± 9480
Ambient temperature × bar size (E_{13})	-4650 ± 9480
Wind velocity × bar size (E_{23})	-100 ± 9480
Ambient temperature × wind velocity × bar size (E_{123})	4700 ± 9480

Unreplicated Factorial Designs. There are times when it is either not feasible or not desirable to include replication in a two-level factorial design. In such cases, it is therefore not possible to obtain a direct estimate of the experimental error; as a result, it becomes more difficult to assess the relative importance of the variable effects. There are, however, at least two methods that can be employed to aid in the assessment of the relative importance of variable effects estimated from the results of an unreplicated two-level factorial design. These two methods are:

- The use of normal probability plots of the effect estimates
- The use of higher-order interaction effect estimates as a means to obtain an estimate of the experimental error

These methods are discussed in Ref 7 and 25.

Two-Level Fractional Factorial Designs

Although the class of two-level factorial designs appears to be an efficient way to deal simultaneously with several factors, this efficiency quickly disappears as the number of variables to be studied grows. Because the two-level factorial requires the consideration of all possible combinations of k variables at two levels each, a ten-variable experiment would require $2^{10} = 1024$ tests.

In dealing with phenomena involving continuous variables, the relationship that describes the influence of the variables on a response of interest often constitutes a relatively smooth response surface. When dealing with qualitative (discrete) variables, it is usually the case that the responses are similar at different levels of such variables. Therefore, the higher-order variable interactions are often very small or negligible in magnitude. In fact, interaction effects involving three factors or more can be ignored for the purpose of screening out the much more important main effects and two-factor interaction effects from a limited number of tests.

Experimentation with large numbers of variables generally arises out of uncertainty as to which variables have the dominant influence on the response of interest. In the end, however, only a subset of all these variables will be proved to be important. This phenomenon is referred to as the sparsity of variable effects (Ref 8). If this is the case, one should be able to conduct fewer tests than required for the full factorial without much loss of relevant information.

Consequences of Fractionation

In the rail steel bar problem, three variables (ambient temperature, wind velocity, and bar size) were studied to determine their possible effect on the ultimate tensile strength of the welded bars. A 2^3 full factorial design was run, and the three main effects, three two-factor interaction effects and the one three-factor interaction effect could all be estimated separately. Suppose now that the investigator had wished to consider a fourth variable, type of welding flux, but that the full factorial, $2^4 = 16$ tests, could not be considered. Rather, only 8 tests can be run. Is it possible to conduct an experiment on 4 factors with only 8 tests, and if so, what useful information can be obtained from the results?

Based on the assumption about the negligible third and higher-order interaction effects, one could consider assigning the column of plus and minus signs associated with the **123** interaction to be the fourth variable and estimate the average main effect of variable **4** using this column. In using the **123** column to introduce a fourth variable into the experiment, the new design matrix that defines the 8 tests to be conducted becomes:

Test	Variables			
	1	2	3	4 (123) ^(a)
1	-	-	-	-

Examination of the calculation matrix in Table 14 reveals that many of the columns are identical. In particular, of the 16 columns, only 8 are unique; each unique column appears twice. The following pairs of variable effects are represented in the calculation matrix by the same column of plus and minus signs:

1 and 234
2 and 134
3 and 124
4 and 123
12 and 34
13 and 24
23 and 14
Ave and 1234

What does all this mean? For example, when the **12** column is multiplied by the data, summed, and divided by 4, is the result an estimate of the two-factor interaction **12**? Or the two-factor interaction **34**? Or both? The interactions **12** and **34** are said to be confounded or confused. They are aliases of the unique column of plus and minus signs defined by (+ - - + - - +). Use of this column for effect estimation produces a number (estimate) that is actually the combined total of the two-factor interaction effects **12** and **34**. Similarly, **1** and **234** are confounded effects, **2** and **134** are confounded effects, and so on. It seems that the innocent act of using the **123** column to introduce a fourth variable into a 2^3 full factorial scheme has created a lot of confounding among the variable effects, but if all the three-factor interactions are negligible, one obtains clear estimates of all 4 main effects from only 8 tests.

The 2^{k-p} Fractional Factorial Designs. The four-variable, eight-test, two-level experiment discussed thus far is referred to as a two-level fractional factorial design because it considers only a fraction of the tests defined by the full factorial. In this case, a one-half fraction design has been created. It is commonly referred to as a 2^{4-1} fractional factorial design. It is a member of the general class of 2^{k-p} fractional factorial designs. In these designs, the following factors must be considered:

- k variables are examined in 2^{k-p} tests
- Require that p of the variables be introduced into the full factorial in $k-p$ variables
- Assign them to interaction effects in the first $k-p$ variables. This assignment is done through the use of relationships known as generators (Ref 7, 8)
- These generators can then be used to establish the defining relationship (Ref 7, 8), which completely reveals the confounding/alias structure of the experimental design

Resolution of Two-Level Fractional Factorial Designs. As discussed previously, the introduction of additional variables into full two-level factorials gives rise to confounding or aliasing of variable effects. It would be desirable to make this introduction in such a way as to confound low-order effects (main effects and two-factor interactions)--not with

each other but with higher-order interactions. Then, under the assumption that third and higher-order interactions can be neglected, the low-order effects become, in a sense, unconfounded by this assumption.

To illustrate, consider the study of 5 variables in just 16 tests (the full factorial would require $2^5 = 32$ tests). One additional variable--the fifth variable--must be introduced into a $2^4 = 16$ run base design. Any of the interactions in the first 4 variables could be used for this purpose: **12, 13, 14, 23, 24, 34, 123, 124, 134, 234, 1234**. If any one of the two-factor interactions are used, for example, **5 = 12**, then the design generator becomes **I = 125**, which is also the defining relationship. Therefore, at least some of the main effects will be confounded with two-factor interactions, namely, **1 = 25, 2 = 15, 5 = 12**.

Selecting Preferred Generators. If any one of the three-factor interactions is used to introduce the fifth variable, the situation is greatly improved, at least for the estimation of main effects. For example, if **5 = 123**, then **I = 1235** is the generator and defining relationship; therefore, some main effects are confounded with, at worst, three-factor interactions, while two-factor interactions are confounded with each other, for example:

1 = 235
2 = 135
3 = 125
5 = 123
12 = 35
13 = 25
23 = 15

If the four-factor interaction in the first 4 variables is used to introduce the fifth variable, an even more desirable result is obtained (the best under these circumstances): **5 = 1234**. The generator and defining relationship is **I = 12345**. Therefore:

1 = 2345
2 = 1345
3 = 1245
4 = 1235

5 = 1234
12 = 345
13 = 245
14 = 235
15 = 234
23 = 145
24 = 135
25 = 134
34 = 125
35 = 124
45 = 123

In this last case, all main effects are confounded with four-factor interactions, and all two-factor interactions are confounded with three-factor interactions.

Concept of Resolution. The varying confounding structures produced by using different orders of variable interactions to introduce the fifth variable in the example above are described by the concept of the resolution of fractional factorial designs. The resolution of a two-level fractional factorial design is defined to be equal to the number of letters (numbers) in the shortest-length word (term) in the defining relationship, excluding **I**. If the defining relationship of a certain design is **I = 124 = 135 = 2345**, then the design is of Resolution III. If the defining relation of a certain design is **I = 1235 = 2346 = 1456**, then the design is of Resolution IV. The last design examined above, which had the defining relationship **I = 12345**, is a Resolution V design. These concepts can be summarized as follows:

- If a design is of Resolution III, this means that at least some main effects are confounded with two-factor interactions
- If a design is of Resolution IV, this means that at least some main effects are confounded with three-factor interactions, while at least some two-factor interactions are confounded with other two-factor interactions
- If a design is of Resolution V, this means that at least some main effects are confounded with four-factor interactions, and some two-factor interactions are confounded with three-factor interactions

Example 9: Design Resolution/Selection of Generators.

A 2^{6-2} fractional factorial design is set up by introducing variables **5** and **6** via **5 = 123**, **6 = 1234**. What is the resolution of this design?

The design generators are $\mathbf{I} = 1235 = 12346$, with the defining relationship $\mathbf{I} = 1235 = 12346 = 456$. Therefore, the design is of Resolution III.

What would the resolution be if the generators were $\mathbf{5} = 123$ and $\mathbf{6} = 124$? Because the defining relationship is $\mathbf{I} = 1235 = 1246 = 3456$, the design is of Resolution IV. It is clear that the selection of the proper design generators is very important.

Additional Observations on Design Resolutions. From the above discussion on design resolution, several observations can be made:

- Higher-resolution designs seem more desirable because they provide the opportunity for low-order effect estimates to be determined in an unconfounded state, assuming higher-order interaction effects can be neglected
- The more variables considered in a fixed number of tests, the lower the resolution of the design becomes
- There is a limit to the number of variables that can be considered in a fixed number of tests while maintaining a prespecified resolution requirement
- No more than $(n - 1)$ variables can be examined in n tests (n is a power of 2, for example, 4, 8, 16, 32, . . .) to maintain a design resolution of at least III. Such designs are commonly referred to as saturated designs. Examples are 2^{3-1} , 2^{7-4} , 2^{15-11} , 2^{31-26} . For saturated designs, all interactions in the base design variables are used to introduce additional variables

Importance of Sequential Experimentation

In the early stages of an investigation, it often seems that many variables are of potential importance. A project group or task force can draw up a list of 5 to 15 or more variables. In the final analysis, perhaps only 2 or 3 of these variables will prove to be important. The problem is, Which ones? The first task at hand is to conduct some experiments that will quickly reduce the number of variables under study to the few seemingly important ones that will then be the focus of further experimentation. For this screening task, two-level fractional factorial designs constitute a powerful and efficient tool. If the investigator attempts to get his arms around the entire problem by designing one comprehensive experiment, the resource requirements will probably be extensive, and the final results of the experiment may be inconclusive because of poor selection of variable levels and/or a poorly controlled experimental environment precipitated by a large experiment.

It would be wise to take a sequential approach, building up knowledge more gradually through a series of related experiments. In this regard, two-level fractional factorial designs serve as useful building blocks in a course of sequential experimentation. This notion is important to ensure that a lack of knowledge early in an investigation will not lead to the waste of experiment resources—for example, inappropriate variables or variable levels chosen in the context of one large experiment. It is possible to identify families of experiments that combine or piece together well. A key point here is that these related experiments can provide several different alternatives for a second experiment, depending on the results and inferences drawn from the first experiment. The sequential assembly aspect of related experiments is discussed below.

Example 10: Notion of Families of Fractional Factorials.

All 16 one-sixteenth fractions of the 2^7 factorial are related through the generators $\mathbf{I} = \pm 124$, $\mathbf{I} = \pm 135$, $\mathbf{I} = \pm 236$, $\mathbf{I} = \pm 1237$. The terms remain the same, only the signs are changed for different fractions. The original design (all + signs on the generators) is called the principal fraction. The remaining 15 are the alternate fractions.

The key point is that, depending on the interpretation of the results of the principal fraction, any one of several other alternate fractions can be chosen to achieve a particular result when the two fractions are combined. A general strategy used in running successive experimental designs is to choose judiciously among the members of a given family of fractional factorials.

Clearly, given the principal fraction, several alternatives are available among the remaining alternate fractions, each providing a different set of information/effect estimates from the combined design. Table 15 provides some relevant information concerning the family of fractional factorials associated with a seven-variable experiment using eight-test designs.

Table 15 2^{7-4}_{III} family of fractional factorials

Fraction	Generators	When combined with principal fraction gives:
Principal	$I = 124 \ I = 135 \ I = 236 \ I = 1237$...
A1	$I = -124 \ I = -135 \ I = -236 \ I = -1237$	All main effects
A2	$I = -124 \ I = -135 \ I = 236 \ I = -1237$	1, 12, 13, 14, 15, 16, 17
A3	$I = -124 \ I = 135 \ I = -236 \ I = -1237$	2, 12, 23, 24, 25, 26, 27
A4	$I = 124 \ I = -135 \ I = -236 \ I = -1237$	3, 13, 23, 34, 35, 36, 37
A5	$I = -124 \ I = 135 \ I = 236 \ I = 1237$	4, 14, 24, 34, 45, 46, 47
A6	$I = 124 \ I = -135 \ I = 236 \ I = 1237$	5, 15, 25, 35, 45, 56, 57
A7	$I = 124 \ I = 135 \ I = -236 \ I = 1237$	6, 16, 26, 36, 46, 56, 67
A8	$I = 124 \ I = 135 \ I = 236 \ I = -1237$	7, 17, 27, 37, 47, 57, 67

Orthogonal Arrays

The theory of fractional factorial designs was first worked out by Finney (Ref 26) and Rao (Ref 27). Many highly fractionated designs were introduced by Tippet (Ref 28), Plackett and Burman (Ref 29), and others. Some of these were referred to as magic squares and orthogonal arrays. Two-level and three-level fractional factorial designs gained widespread attention and industrial application, beginning in the 1950s. Box and Hunter (Ref 7) provided much useful guidance to the practitioner in the adroit use of these experimental design structures.

In the late 1970s, the use of orthogonal arrays for quality design and improvement by Taguchi (Ref 4) and others gained widespread acceptance in industry. This has led to considerable discussion concerning the relative merits of these designs and the methods of design selection *vis-à-vis* the methodology of the more general class of fractional factorial designs. In particular, it is important to examine the philosophical framework and interpretation of these similar (often identical) design structures.

Issue of Confounding. To many, the most significant property of the designs is orthogonality, that is, the ability to separate out the individual effects of several variables on a response of interest. The term orthogonal arrays as used by Taguchi implies having this property of orthogonality or producing effects that are not confounded. In fact, whenever anything less than a full factorial is under consideration, confounding or mixing of effects is present by definition. Such confounding can only be removed by assumptions made about the physical system and confirmed through some analyses of the results.

Similarly, when two-level factorials are fractionated, the ability to determine all the interactions among a set of factors is lost. However, judicious fractionation leads to the ability to obtain knowledge on low-order interactions under the assumption that higher-order interactions are of negligible importance. Because the orthogonal arrays, as applied to Taguchi methods, are highly fractionated factorial designs, the information these arrays produce is a function of two elements: the nature of their confounding patterns and the assumptions made about the physical system they are applied

to. Often, Taguchi's use of linear graphs for design selection fails to produce the highest possible degree of resolution, as the following example will illustrate.

Example 11: Examination of the Use of an $L_{16}(2^{15})$ Orthogonal Array

(Ref 4). The notation for various orthogonal arrays by Taguchi and Wu is generally of the following form for designs without mixing levels $L_n(r^m)$, where n is number of tests, r is number of levels of each factor, and m is the maximum number of factors, including selected interactions, that the design can study. For example, $L_{16}(2^{15})$ refers to a design with 16 tests to study up to 15 two-level factors and/or interactions. An $L_{16}(2^{15})$ orthogonal array is given in Table 16.

Table 16 An $L_{16}(2^{15})$ orthogonal array

(a) e = estimate of error

In this application of the $L_8(2^{15})$ orthogonal array, the following assignments have been made:

- Eight columns have been assigned to variable main effects A, B, C, D, E, F, G, H
- Three columns have been assigned to two-factor interactions $A \times B, B \times D, A \times D$
- Four columns have been assigned to the estimation of error

Close examination of the $L_{16}(2^{15})$ orthogonal array shows that the columns assigned to $E, G, H,$ and C are the following products of the columns assigned to $D, B, A,$ and F :

5 = 234 <i>(E = B × A × F)</i>
7 = 123 <i>(G = C × B × A)</i>
6 = -14 <i>H = -(C × F)</i>
8 = -1234 <i>D = -(C × B × A × F)</i>

It follows then from the associated defining relationship that this $L_{16}(2^{15})$ orthogonal array is not only a 2^{8-4} fractional factorial but also a Resolution III 2^{8-4} design. This is surprising because it is possible to design a 16-run, two-level fractional factorial to examine eight variables (Resolution IV) using generators such as:

5 = 234 (I = 2345)
6 = 134 (I = 1346)
7 = 123

(I = 1237)
8 = 124 (I = 1248)

The $L_{16}(2^{15})$ orthogonal array under examination, when viewed as a 2^{8-4} fractional factorial design, produces the following 16 linear combinations of effects, which can be estimated from the data. It is assumed that three-factor interactions and higher can be neglected:

l_0 estimates	I (mean)
l_1 estimates	1 - 46 - 58
l_2 estimates	2
l_3 estimates	3
l_4 estimates	4 - 16 - 78
l_5 estimates	12 + 37
l_6 estimates	13 + 27
l_7 estimates	6 - 14 - 57
l_8 estimates	23 + 45 + 17 + 68
l_9 estimates	24 + 35
l_{10} estimates	34 + 25
l_{11} estimates	7 - 48 - 56
l_{12} estimates	26 + 38
l_{13} estimates	36 + 28
l_{14} estimates	5 - 18 - 67

I_{15} estimates	8 - 15 - 47
--------------------	-------------

It is interesting to note the following for this particular 2^{8-4} fractional factorial:

- Only two of the eight main effects are not confounded with two-factor interactions. The other six main effects are each confounded with two two-factor interactions
- One of the desired two-factor interactions (**23**) is confounded with three other two-factor interactions
- The four columns assigned to the estimation of error each represent pairs of two-factor interactions confounded with each other

An Alternate $L_{16}(2^{15})$ Orthogonal Approach. It would appear that the $L_{16}(2^{15})$ orthogonal array using the generators given below is more suitable for the purposes of Taguchi methods (or any methods for that matter), particularly given the assumptions generally made about interaction effects:

5 = 234
6 = 134
7 = 123
8 = 124

From this 2^{8-4} fractional factorial design, the linear combination of effects (ignoring interactions of three or more factors) given in Table 17 would result.

Table 17 Linear combination of effects obtained from 2^{8-4} fractional factorial design

		Effect name in Taguchi experiment
I_0 estimates	$I(\text{mean})^{(a)}$	
I_1	<u>1</u>	<i>D</i>
I_2	<u>2</u>	<i>B</i>
I_3	<u>3</u>	<i>A</i>
I_4	<u>4</u>	<i>F</i>

l_5	<u>12</u> + 37 + 48 + 56	$B \times D$
l_6	<u>13</u> + 46 + 37 + 58	$A \times D$
l_7	14 + 36 + 28 + 57	$e^{(b)}$
l_8	<u>23</u> + 45 + 17 + 68	$A \times B$
l_9	24 + 35 + 18 + 67	$e^{(b)}$
l_{10}	34 + 25 + 16 + 78	$e^{(b)}$
l_{11}	<u>7</u>	H
l_{12}	<u>8</u>	C
l_{13}	<u>6</u>	G
l_{14}	<u>5</u>	E
l_{15}	15 + 25 + 47 + 38	$e^{(b)}$

(a) Underscored effects identify corresponding effects. For example, 1 is D , 2 is B , and so on, in Taguchi's experiment.

(b) e = estimate of error

The following conclusions can be drawn from Table 17:

- All eight main effects are confounded with three-factor and higher--only two previously
- All three desired two-factor interactions are confounded with three other two-factor interactions--only one previously
- All four error estimates are a set of four confounded two-factor interactions; previously, they were sets of two confounded two-factor interactions. This is a trade-off for the estimation of two of the desired two-factor interactions: $B \times D$ and $A \times D$

Choice of Variables in Calculation Matrix. When fewer than $k = n - 1$ variables are studied in $2^{k-p} = n$ tests, some choice exists in terms of how variables (main effects) are assigned to columns in the $L_n(2^k)$ array (the calculation matrix). Some choices are often better than others in terms of the resulting design resolution. Under the Taguchi approach to design of experiments, the philosophy toward interaction effects is quite different. As a result, the bottom line is that unless they are expressly identified and assigned to the orthogonal array, they are assumed to be neglectable. If such an attitude is adhered to, it is perhaps of even greater importance to place emphasis on design resolution and the careful examination of the alias structure of the experimental design. When higher-resolution designs (arrays) are available, it is

of utmost importance to seek them out in an effort to protect the assumptions used. Again, Example 11 demonstrates the importance of design resolution and the judicious choice of design generators. In the context of Taguchi's approach to design of experiments, this is even more important because the sequential assembly concept is not used; that is, single experiments tend to be employed on any given problem.

Statistical Quality Design and Control

Richard E. DeVor, University of Illinois, Urbana-Champaign; Tsong-how Chang, University of Wisconsin, Milwaukee

Implementing Robust Design

Recently, a number of different approaches have been proposed as possible ways to implement the robust design concept of Taguchi. These vary from purely analytical approaches, to computer simulation using product/process mathematical models and/or Monte Carlo methods, to the use of physical experimentation. In most of these approaches, the use of experimental design strategies, including two-level and multilevel factorial and fractional factorial designs and orthogonal arrays, has been extensive.

Taguchi views the design process as evolving in three distinct phases or steps:

- System design
- Parameter design
- Tolerance design

It is perhaps this broad umbrella that he places over his concepts and methods for quality design and improvement that makes his approach so widely accepted by the engineering community. As discussed previously, Taguchi considers engineering design as the central issue and statistical methods as just one of several tools to accomplish his objectives in engineering.

In addition to the different approaches to generating data on product/process performance, the issue of the specific measures of performance to use in the facilitation of parameter design needs to be considered. Taguchi and his colleagues make extensive use of the signal-to-noise ratio as a measure of performance. Others evaluate the mean and the variance or standard deviation of performance separately. The relative merits of these varying approaches with regard to performance evaluation will be discussed later in this article. The separate analysis of mean response and variation in response is discussed below.

Degree of Control

The issue of the control of a certain factor is actually one of economics; therefore, any factor might be thought of in terms of its degree of control rather than as controllable or not controllable. Suppose that an injection-molding process is under consideration because of a part shrinkage problem. A brainstorming session might lead to the following list of factors as potentially having an influence on part shrinkage:

- Cycle time
- Percentage of regrind versus virgin raw material
- Gate configuration
- Holding pressure
- Screw speed
- Mold temperature
- Cavity surface finish
- Raw material moisture content
- Raw material melt flow index
- Mold cooling water temperature

Although any or all of these factors can influence part shrinkage, they are not all controlled or manipulated to the same degree or with the same ease, economically. Some of these factors can be controlled at the engineering design process--for example, the gate configuration or the cavity surface finish of the mold. Others are controllable at the molding machine--for example, screw speed or cycle time. Still others are properties of the incoming raw material and are thus under the control of the supplier--for example, melt flow index. Finally, certain factors can be best categorized as defining part of the environment in which the process must function--for example, mold cooling water temperature and percentage of regrind versus virgin raw material. Two case studies will be discussed that exemplify some of the different ways in which the concept of parameter design can be implemented to develop robust product and process designs.

Analytical Approaches to Parameter Design

It is important to keep a broad perspective on the contributions of Taguchi and the wide variety of ways in which they can be utilized. Perhaps the single overarching concept that drives the philosophies of Taguchi is the importance placed on the consistency of performance of products and processes, that is, the importance of variation reduction. In essence, as designs are formulated and output performances evaluated, either analytically or experimentally, as much or more emphasis should be placed on variation in performance as on performance on average. There are many ways to invoke this overarching concept.

Although much of the knowledge used in a given design situation is derived from experimentation, an ever-expanding baseline of knowledge exists that is being derived from first principles/physical laws and the utilization of sophisticated modeling methods such as finite-element modeling. As closed form solutions become available, it becomes possible to evaluate them analytically or numerically using classical optimization methods. The performance function should be examined in terms of both its expected value and its variance function. Searching the variance function to find those values for the design/control variables that minimize the variance in performance then amounts to invoking the parameter design method.

Example 12: Parameter Design Methods Applied to Analysis of Effort Required to Close an Automobile Door

(Ref 30). An explicit model is used for the mean square error of design performance in an automobile door-closing-effort problem to identify the values of the design parameters that provide the most consistent design configuration (minimum variance) while maintaining an acceptable level of average performance. In this case study, the following logic/methodology is employed.

Problem Formulation. The first step in any design optimization problem is to formulate the design performance measure of interest. In this case study, automobile door fit is the issue, particularly the sensitivity of the closing effort to variations in door positioning as it is hung in place. Figure 44 illustrates a car door and the locations of the three positioning points used to hang the door. The closing effort is a function of the compression of the weatherstripping

around the door periphery. The closing effort can be expressed analytically as a function of the weatherstripping diametral stiffness, the weatherstripping diameter and length, and the nominal values of the door position points that define the door/frame gap. The basic design problem is then to find the nominal values for the door position points that minimize the variation in closing effort as a result of the tolerance range assigned to the door position points. This problem was formulated in an attempt to exploit the underlying nonlinearities in the system to improve performance consistency.

Fig. 44 Schematic of an automobile door showing locations (solid circles) of three positioning points used to hang the door

Model Derivation. Under the assumption that the door gap is linearly proportional to the door position point locations, it is possible to derive the door-closing effort (in stored energy) as a quadratic function of the position point locations. The position location points are the control factors in this problem. The quadratic function for closing effort as a function of the three hanging positions has several unknown parameter values. Although the closing effort will clearly vary as a function of variation from car to car in the weatherstripping thickness, car body, size, and so on, only the variation in the door hanging position from car to car was examined in this case study.

Model Fitting. The parameters of the quadratic function for closing effort were estimated by first calculating the door gap at 15 points around the door as a function of variations in the door hanging positions and then using the calculated gap values to determine the closing-effort values. The variations in the hanging position control factors were introduced using a three-level factorial design, which required a total of 27 evaluations of the gap and the stored energy at each of the 15 locations around the door. These data were then used to estimate the coefficients of the quadratic closing-effort function.

Design Optimization. The variance of the closing-effort quadratic function can now be derived analytically, and this variance function can be subjected to a classical optimization routine. Such an optimization algorithm will seek the values of the three door position locations that minimize the variance of the closing effort. This optimization is subject to the constraint that the mean closing effort is less than or equal to a prespecified target value. The result is the determination of the nominal values for the design/control factors, that is, the door positioning locations that minimize the car-to-car closing-effort variation because of variation in these locations. In this design optimization problem, the control factors are the nominal values for the door position locations, and the noise factors are the tolerance/variations in the door position locations.

Figure 45 shows a plot of the derived functional relationship between closing effort and the location of point 1 for positioning the door for fixed values of location points 2 and 3. Figure 45 clearly shows how the parameter design method exploits a basic system nonlinearity by seeking a new nominal value for the location of point 1 that reduces the transmitted variation to the closing effort due to the variation in the location of point 1 about its nominal value.

Fig. 45 Plot of closing effort versus point 1 location for positioning the door shown in Fig. 44 with fixed values of location points 2 and 3

Experimental Approaches to Parameter Design

The parameter design concept can be implemented through physical experimentation in many different ways. The following example illustrates the explicit use of an inner/outer design for robust design. The example was developed from the results of a larger experiment and is presented to demonstrate how simple experiments such as two-level factorial designs can be used to study and improve the performance of an assembly process using the concept of robust design.

Example 13: Optimization of Automotive Fuel Gage Reading to Actual Fuel Tank Quantity.

Customer complaints regarding the difference between the fuel gage reading and the actual amount of fuel in the tank led to an investigation of the process of gage calibration. Seven variables were tentatively identified as being of possible importance to the position (% deflection or fallback) of the indicator in the fuel gage.

Initial Design of Experiments. A 2^{7-3} fractional factorial design experiment was constructed and carried out. A portion of the results will be examined that involve four of the seven variables determined to be the most important. These four variables are:

Variable No.	Variable	Low level	High level
1	Spring tension	Loose	Tight
2	Method of pointer location	Visual	Other (standard)
3	Bimetal hook twist	Vendor A	Vendor B
4	Bimetal bracket bend	90°	93°

Variables 1 and 2 describe adjustments that can be made during the calibration process on the assembly line. Variables 3 and 4 describe the condition (considered undesirable) of certain purchased parts that are assembled into the gage and may

affect the calibration process. The 2^{7-3} fractional factorial design was collapsed into a 2^4 full factorial design to study the effects of these variables, as they are purposely changed, on the response in question.

Table 18, the design matrix, lists the settings for the 16 tests conducted in terms of the four variables defined above. The tests are listed in standard order, although they were actually run in a randomized test sequence.

Table 18 Design matrix for fuel gage experiment of Example 13

Test number	x_1	x_2	x_3	x_4	Y, %
1	Loose	Visual	Vendor A	90	14
2	Tight	Visual	Vendor A	90	10
3	Loose	Other	Vendor A	90	7
4	Tight	Other	Vendor A	90	8
5	Loose	Visual	Vendor B	90	18
6	Tight	Visual	Vendor B	90	9
7	Loose	Other	Vendor B	90	7
8	Tight	Other	Vendor B	90	10
9	Loose	Visual	Vendor A	93	15
10	Tight	Visual	Vendor A	93	9
11	Loose	Other	Vendor A	93	14
12	Tight	Other	Vendor A	93	7
13	Loose	Visual	Vendor B	93	7
14	Tight	Visual	Vendor B	93	12
15	Tight	Other	Vendor B	93	9
16	Tight	Other	Vendor B	93	12

The main effects of each of the four factors, as well as the two-, three-, and four-factor interactions, were estimated from the data and are listed below:

$E_1 = -2.50$ $*E_2 = 0.00$ $E_3 = -1.75$ $E_4 = 3.00$	
$*E_{12} = 0.50$ $E_{13} = 1.75$ $E_{14} = -1.00$ $E_{23} = 2.25$ $*E_{24} = 0.50$ $E_{34} = -1.25$	
$*E_{123} = 0.75$ $E_{124} = -2.50$ $*E_{134} = 0.75$ $*E_{234} = 0.25$	$E_{1234} = -2.25$

The results of the larger experiment, in fact, showed that these four variables tended to exhibit the stronger effect estimates, both main effects and interactions. A normal probability plot of the estimated effects could be interpreted as suggesting that only the effect estimates indicated by the asterisk might be considered insignificant. This interpretation leaves the investigator somewhat perplexed as to what exactly to do next. Many interactions seem important, yet it is not at all clear how the process can best be adjusted/alterd.

It would appear that the main effects of variables 1 and 4 might be two of the more important effects:

- $E_1 = -2.50$, implies that, on the average, tighter spring tension reduces fallback (deflection)
- $E_4 = +3.00$, implies that larger bimetal bracket bends (93°) increase deflection, which is undesirable

The latter inference suggests that closer adherence to the 90° bend, which is the desired nominal value, may have to be requested from the bimetal bracket supplier. This essentially means that the supplier would be required to tighten the tolerance on this angle. Rather than taking this more costly approach, it might be useful to consider the variation in this part dimension as a noise variable and then determine how the transmission of the variation in the bimetal bracket bend could be reduced through the manipulation of control factors during the calibration process.

Alternative Experimental Design and Analysis. A more thoughtful examination of the four variables under study seems to indicate that they fall into two basic categories. The first category consists of:

- *Variable 1:* Spring tension
- *Variable 2:* Method of pointer location

The second category consists of:

- *Variable 3:* Bimetal hook twist
- *Variable 4:* Bimetal bracket bend

Variables 1 and 2 can be easily adjusted at the discretion of the operator/setup person. Variables 3 and 4 describe certain aspects of the condition of two purchased parts. Although the vendors have been given certain requirements, strong control is not exercised over these factors (which determine the condition of the parts coming in) without tightening the

specification requirements--a costly proposition. Therefore, these two variables might be considered to be noise variables, and perhaps the robust design/parameter design concept can be used to see how adjustments in variables 1 and 2 could be made to reduce the transmitted variability due to variables 3 and 4.

As a result, instead of thinking in terms of a 16-run experiment design that considers four variables at two levels each, one should think in terms of two 2^2 factorial experiments:

- The inner design is a 2^2 factorial in the two controllable variables (spring tension and method of pointer location)
- The outer design is a 2^2 factorial in the two noise variables (bimetal hook twist and bimetal bracket bend)

The outer design is conducted at each of the four unique variable settings of the inner design. A graphical representation of this experiment design is shown in Fig. 46. The numbers in the corners of each of the four outer design squares represent the fallback results for each of the 16 unique trails. Referring to the data in Fig. 46, \bar{Y} and σ_Y , the mean and standard deviation of the % deflection, are determined at each of the four test combinations of the inner design:

Test no.	X_1	X_2	\bar{Y}	σ_Y
1	-	-	12.0	2.94
2	+	-	9.0	3.37
3	-	+	11.5	4.8
4	+	+	9.5	2.08

Fig. 46 Inner/outer experimental design structure for the fuel-gage study data in Table 18. Numbers at corners of outer design squares are fallback (% deflection) values, Y .

By analyzing the above responses (average fallback and standard deviation of fallback) separately, the settings/values can be determined for the control variables that minimize average fallback and give rise to minimum variation in fallback, that is, the most robust process design.

Results. Figures 47 and 48 illustrate the results of the analyses. The interpretation of the results is as follows:

- In terms of average response, % deflection is reduced by increasing spring tension (Fig. 47). This reduction is about the same for both methods of pointer location. On the average, the pointer location method has little effect on % deflection
- In terms of standard deviation, it is best to use the other (standard) method of pointer location along with tighter spring tension (Fig. 48)

It appears that the nominal response can be controlled by the manipulation of spring tension, while the variation in response is controlled by manipulation of the method of pointer location.

Fig. 47 Effect of control factors on average performance. Numbers at corners of square are the means of the % deflection, \bar{Y} .

Fig. 48 Effect of control factors on variation in performance. Numbers at corners of square are the standard deviations of the % deflection, σ_Y .

 - candela
- **CFA**
 - crossed-field amplifier
- **CFRP**
 - carbon fiber-reinforced plastic
- **Ci**
 - curie
- **CID**
 - charge-injected device
- **CIE**
 - Commission Internationale de l'Eclairage (International Commission on Illumination)
- **CL**
 - control limit; confidence level
- **CMM**
 - coordinate measuring machine
- **CMS**
 - coordinate measuring system
- **COD**
 - crack opening displacement
- **CRT**
 - cathode ray tube
- **C-SAM**
 - C-mode scanning acoustic microscopy
- **cSt**
 - centiStokes
- **CT**
 - computed tomography
- **CuSum**
 - cumulative sum
- **CW**
 - continuous wave
- **d**
 - deuteron
- ***d***
 - used in mathematical expressions involving a derivative (denotes rate of change); depth; diameter
- ***D***
 - diameter; duration; dislocation density
- ***da/dN***
 - fatigue crack growth rate
- **DAC**
 - digital-to-analog converter
- **dB**
 - decibel
- **dBae**
 - decibel of acoustic emission amplitudes
- **dc**
 - direct current
- **DCC**
 - direct computer control
- **diam**

- diameter
- **DIN**
 - Deutsche Industrie-Normen (German Industrial Standards)
- **DIP**
 - dual-in-line package
- **DLM**
 - digital light meter
- **dpi**
 - dots per inch
- **DR**
 - digital radiography; digital radiograph
- *e*
 - natural logarithm base, 2.71828; random error
- *E*
 - modulus of elasticity; electric field strength; emissive power; electromotive force; energy counts (acoustic emission); applied voltage
- **EC**
 - eddy current
- **ECP**
 - electric current perturbation
- **EDM**
 - electrical discharge machining
- **EMA**
 - electromagnetic acoustic (transducer)
- **ENSIP**
 - Engine Structural Integrity Program
- **EPA**
 - Environmental Protection Agency
- **Eq**
 - equation
- *et al.*
 - and others
- **ET**
 - eddy current testing
- **eV**
 - electron volt
- **EWMA**
 - exponentially weighted moving average
- *f*
 - frequency; transfer function
- *F*
 - eddy current inspection test frequency
- **FERPIC**
 - ferroelectric photoconductor image camera
- **FET**
 - field-effect transistor
- **FFT**
 - fast Fourier transform
- **FID**
 - flame ionization detector
- **Fig.**
 - figure
- **fm**
 - femtometer
- **FM**
 - frequency modulation
- **FMR**

- ferromagnetic resonance
- **FR**
 - felicity ratio
- **FRP**
 - fiber-reinforced plastic
- **ft**
 - foot
- **ftc**
 - footcandle
- **ft-L**
 - footlambert
- **g**
 - gram
- **G**
 - gauss
- **G_D**
 - film gradient
- **GBq**
 - gigabecquerel
- **GPa**
 - gigapascal
- **GTO**
 - gate turnoff
- **Gy**
 - gray (unit of absorbed radiation)
- **h**
 - convection heat transfer coefficient
- **h**
 - hour
- **H**
 - magnetic field strength
- **H**
 - magnetic field vector
- **HAZ**
 - heat-affected zone
- **HB**
 - Brinell hardness
- **HIP**
 - hot isostatic pressing
- **HNDT**
 - holographic nondestructive test
- **HR**
 - Rockwell hardness (requires scale designation, such as HRC for Rockwell C hardness)
- **HSL**
 - hue, saturation, luminance
- **i**
 - $\sqrt{-1}$ for a complex variable; a summation index
- **i**
 - unit vector along the x -axis
- **I**
 - intensity; electrical current
- **$\langle I \rangle$**
 - average intensity
- **IACS**
 - International Annealed Copper Standard
- **IBIS**

- integrated blade inspection system
- **IC**
 - integrated circuit
- **ID**
 - inside diameter
- **IF**
 - intermediate frequency
- **IGA**
 - intergranular attack
- **IMPATT**
 - impact avalanche transit time
- **in.**
 - inch
- **IQI**
 - image quality indicator
- **IR**
 - infrared
- ***j***
 - $\sqrt{-1}$ for a complex variable; a summation index
- **j**
 - unit vector along the y-axis
- **J**
 - joule
- ***k***
 - thermal conductivity; wave number
- **k**
 - unit vector along the z-axis
- ***K***
 - stress intensity factor; kernel
- ***K_c***
 - plane-stress fracture toughness
- ***K_{Ic}***
 - plane-strain fracture toughness
- ***K_{Isc}***
 - threshold stress intensity for stress-corrosion cracking
- **kg**
 - kilogram
- **km**
 - kilometer
- **kPa**
 - kilopascal
- **ksi**
 - 1000 lb (1 kip) per square inch
- **kV**
 - kilovolt
- **kVp**
 - kilovolt peak
- ***l***
 - average rate of occurrence of defects per sample; length
- ***L***
 - length; likelihood (function)
- **lb**
 - pound
- **LCC**
 - life cycle cost
- **LCF**

- low cycle fatigue
- **LCL**
 - lower control limit; lower confidence limit
- **LED**
 - light-emitting diode
- **LEL**
 - lower explosive limit
- **LINAC**
 - linear accelerator
- **LLW**
 - leaky Lamb wave
- **lm**
 - lumen
- **ln**
 - natural logarithm (base e)
- **LNG**
 - liquified natural gas
- **LO**
 - local oscillator
- **LPF**
 - low-pass filter
- **lpm**
 - line pairs per millimeter
- **LSP**
 - laser speckle photography
- **LUT**
 - look-up table
- **lx**
 - lux
- **m**
 - meter
- **m**
 - maximum number of factors, including selected interactions, that the design can study
- **M_a**
 - molecular weight of air
- **M_t**
 - molecular weight of tracer gas
- **MARSE**
 - measured area under the rectified signal envelope
- **MDL**
 - minimum detectable leakage
- **MFD**
 - magnetic field disturbance
- **mg**
 - milligram
- **Mg**
 - megagram (metric tonne)
- **MIG**
 - metal inert gas (welding)
- **MIL-STD**
 - military standard
- **MIVC**
 - magnetically induced velocity change
- **min**
 - minimum; minute
- **mL**
 - milliliter

- **MLCD**
 - microwave liquid crystal display
- **mm**
 - millimeter
- **MOOT**
 - method of optimal truncation
- **MPa**
 - megapascal
- **mpg**
 - miles per gallon
- **mrem**
 - millirem
- **mSv**
 - millisievert
- **MTF**
 - modulation transfer function
- **mV**
 - millivolt
- **MVp**
 - megavolt peak
- **n**
 - neutrons
- **N**
 - newton
- ***n***
 - index of refraction; fringe number; number of tests
- **\bar{n}**
 - average sample size
- ***n***
 - unit vector normal to the surface
- ***N***
 - number of cycles; summation index; fringe order; length of the near field
- ***N_K***
 - Knudsen number
- ***N_{Re}***
 - Reynolds number
- **NBS**
 - National Bureau of Standards
- **NDE**
 - nondestructive evaluation
- **NDI**
 - nondestructive inspection
- **NDT**
 - nondestructive testing
- **Nd: YAG**
 - neodymium: yttrium-aluminum-garnet (laser)
- **nm**
 - nanometer
- **NMR**
 - nuclear magnetic resonance
- **No.**
 - number
- **NTSC**
 - National Television Systems Committee
- **OD**
 - outside diameter
- **Oe**

- oersted
- **OSHA**
 - Occupational Safety and Health Administration
- **oz**
 - ounce
- ***p***
 - probability
- ***P***
 - pressure
- **Pa**
 - pascal
- **PC**
 - printed circuit
- **PCB**
 - printed circuit board
- **pH**
 - negative logarithm of hydrogen ion activity
- **PH**
 - precipitation hardening
- **PIND**
 - particle impact noise detection
- **PLC**
 - programmable logic control
- **P/M**
 - powder metallurgy
- **PMT**
 - photomultiplier tube
- **POD**
 - probability of detection
- **POFA**
 - probability of false alarm
- **ppm**
 - parts per million
- **ppt**
 - parts per trillion
- **psi**
 - pounds per square inch
- **psig**
 - gage pressure (pressure relative to ambient pressure) in pounds per square inch
- ***Q***
 - calibrated leakage flow
- ***r***
 - number of levels of each factor; original pixel value; radius; range
- **R**
 - roentgen
- ***R***
 - resistance; reflection coefficient; rise time; gas constant; radius
- ***R_a***
 - arithmetic average roughness
- ***R_s***
 - effective shunt resistance
- **rad**
 - radiation absorbed dose
- **radac**
 - rapid digital automatic computing
- **rbe**
 - relative biological effectiveness

- **ref**
 - reference
- **rem**
 - roentgen equivalent man; remainder
- **RF**
 - radio frequency
- **RFEC**
 - remote-field eddy current
- **RGB**
 - red, green, blue
- **RHM**
 - roentgen per hour at one meter
- **RMM**
 - roentgen per minute at one meter
- **rms**
 - root mean square
- **ROC**
 - relative operating characteristic
- **RSSS**
 - radiographic standard shooting sketch
- **RTR**
 - real-time radiography
- **s**
 - second
- **S**
 - siemens
- *S*
 - sensitivity; speed; spacing
- **S**
 - signal input
- **SAE**
 - Society of Automotive Engineers
- **SAM**
 - scanning acoustic microscopy
- **SAT**
 - structural assessment testing
- **SDD**
 - source-detector distance
- **SDP**
 - standard depth of penetration
- **SEC**
 - secondary electron-coupled (vidicon)
- **SEM**
 - scanning electron microscopy
- **sfm**
 - surface feet per minute
- **SiIMPATT**
 - silicon impact avalanche transit time
- **SIT**
 - silicon intensified target
- **SLAM**
 - scanning laser acoustic microscopy
- **SLR**
 - single lens reflex
- **S/N**
 - signal-to-noise (ratio)
- **SOD**

- source-object distance
- **SOF**
 - shape and orientation factor of the flaw
- **SPC**
 - statistical process control
- **SPDT**
 - single pole double throw
- **Sv**
 - sievert
- **std**
 - standard
- ***t***
 - time; thickness
- **T**
 - tesla
- ***T***
 - temperature; transmission coefficient
- **TAB**
 - tape-automated bonding
- **TE**
 - transverse electric (mode)
- **TEM**
 - transmission electron microscopy
- **TEM**
 - transverse electromagnetic (wave)
- **TM**
 - transverse magnetic (mode)
- **TIG**
 - tungsten inert gas (welding)
- **TOF**
 - time of flight
- **tsi**
 - tons per square inch
- **U_g**
 - geometric unsharpness
- **UCL**
 - upper control limit
- **ULCE**
 - unified life cycle engineering
- **USAF**
 - United States Air Force
- **UST**
 - underground storage tank
- **UT**
 - ultrasonic testing
- ***v***
 - degree of freedom; velocity
- ***V***
 - volume; velocity; variance
- **VHS**
 - very high speed
- **VHSIC**
 - very high speed integrated circuit
- **VLSI**
 - very large scale integration
- **vol**
 - volume

- **W**
 - watt
- **WORM**
 - write once read many
- \bar{x}
 - sample mean
- **YIG**
 - yttrium iron garnet
- **yr**
 - year
- **Z**
 - impedance; atomic number; standard normal distribution
- $^{\circ}$
 - angular measure; degree
- $^{\circ}\text{C}$
 - degree Celsius (centigrade)
- $^{\circ}\text{F}$
 - degree Fahrenheit
- \leftrightarrow
 - direction of reaction
- \div
 - divided by
- $=$
 - equals
- \cong
 - approximately equals
- \neq
 - not equal to
- \equiv
 - identical with
- $>$
 - greater than
- \gg
 - much greater than
- \geq
 - greater than or equal to
- ∞
 - infinity
- \propto
 - is proportional to; varies as
- \int
 - integral of
- $<$
 - less than
- \ll
 - much less than
- \leq
 - less than or equal to
- \pm
 - maximum deviation
- $-$
 - minus; negative ion charge
- \times
 - diameters (magnification); multiplied by
- \cdot
 - multiplied by
- $/$
 - per

- %
 - percent
- +
 - plus; positive ion charge
- $\sqrt{}$
 - square root of
- \sim
 - approximately; similar to
- ∂
 - partial derivative
- α
 - thermal diffusivity; angle of incidence
- β
 - angle of refraction
- γ
 - shear strain
- δ
 - skin depth
- Δ
 - change in quantity; increment; range; phase shift
- ϵ
 - normal strain; emissivity; dielectric coefficient
- η
 - viscosity
- θ
 - angle
- λ
 - wavelength; mean free path
- μ
 - linear attenuation coefficient; magnetic permeability; the mean (or average) of a distribution
- $\mu\text{in.}$
 - microinch
- μm
 - micron (micrometer)
- ν
 - Poisson's ratio; frequency
- π
 - pi (3.141592)
- ρ
 - density; resistivity
- σ
 - stress; standard deviation; electrical conductivity
- Σ
 - summation of
- τ
 - shear stress
- ϕ
 - angle of refraction
- ω
 - circular frequency (angular velocity)
- Ω
 - ohm
- **Greek Alphabet**
 - **A, α**
 - alpha
 - **B, β**
 - beta
 - **Γ , γ**

- Γ, γ gamma
 - Δ, δ delta
 - \mathbf{E}, ϵ epsilon
 - \mathbf{Z}, ζ zeta
 - \mathbf{H}, η eta
 - Θ, θ theta
 - \mathbf{I}, ι iota
 - \mathbf{K}, κ kappa
 - Λ, λ lambda
 - \mathbf{M}, μ mu
 - \mathbf{N}, ν nu
 - Ξ, ξ xi
 - \mathbf{O}, \omicron omicron
 - Π, π pi
 - \mathbf{P}, ρ rho
 - Σ, σ sigma
 - \mathbf{T}, τ tau
 - Υ, υ upsilon
 - Φ, ϕ phi
 - \mathbf{X}, χ chi
 - Ψ, ψ psi
 - Ω, ω omega
